KIDDER-NOLAN

THE ARCHITECTS' AND BUILDERS' POCKET-BOOK

A HANDBOOK FOR
ARCHITECTS, STRUCTURAL ENGINEERS,
BUILDERS AND DRAUGHTSMEN

BY

THE LATE FRANK E. KIDDER, C. E., PH. D.

AUTHOR OF "BUILDING CONSTRUCTION AND SUPERINTENDENCE"

COMPILED BY A STAFF OF SPECIALISTS

THOMAS NOLAN, M.S., A.M., EDITOR-IN-CHIEF

FELLOW OF THE AMERICAN INSTITUTE OF ARCHITECTS; PROFESSOR OF ARCHITECTURAL CONSTRUCTION, UNIVERSITY OF PENNSYLVANIA

SIXTEENTH EDITION, REWRITTEN

TOTAL ISSUE, EIGHTY-FOUR THOUSAND

NEW YORK

JOHN WILEY & SONS, INC.

LONDON: CHAPMAN & HALL, LIMITED

1916

The Publishers and the Editor-in-Chief will be grateful to readers of this volume who will call attention to any errors of omission or commission therein. It is intended to make our publications standard works of study and reference, and, to that end, the greatest accuracy is sought. It rarely happens that the early editions of books are free from errors; but it is the endeavor of the Publishers to have them removed, and it is therefore desired that the Editor-in-Chief may be aided in his task of revision, from time to time, by the kindly criticism of readers.

IS RESPECTFULLY DEDICATED TO THOSE WHOSE KINDNESS
HAS ENABLED ME TO PRODUCE IT

TO MY PARENTS

WHO GAVE ME THE EDUCATION UPON WHICH IT IS BASED.

TO MY WIFE

FOR HER LOVING SYMPATHY, ENCOURAGEMENT
AND ASSISTANCE

TO ORLANDO W. NORCROSS

OF WORCESTER, MASS.

WHOSE SUPERIOR PRACTICAL KNOWLEDGE OF ALL THAT
PERTAINS TO BUILDING HAS GIVEN ME A MORE
INTELLIGENT AND PRACTICAL VIEW OF THE
SCIENCE OF CONSTRUCTION THAN I
SHOULD OTHERWISE HAVE
OBTAINED *

* Dedication to First Edition.

EDITORIAL STAFF

EDITOR-IN-CHIEF

THOMAS NOLAN, Professor of Architectural Construction, University of Pennsylvania.

ASSOCIATE EDITORS

HERMAN C. BERRY, Professor of Materials of Construction, University of Pennsylvania.

ROLLA C. CARPENTER, Professor of Experimental Engineering, Cornell University.

J. J. COSGROVE, Consulting Sanitary Engineer.

MALVERD A. HOWE, Professor of Civil Engineering, Rose Polytechnic Institute.

F. H. KINDL, Consulting Engineer, Pittsburgh, Pa.

RUDOLPH P. MILLER, Superintendent of Buildings, Borough of Manhattan, New York, N. Y.

DANIEL E. MORAN, Consulting Engineer, New York, N. Y.

EMILE G. PERROT, of Ballinger & Perrot, Architects and Engineers, Philadelphia, Pa.

N. A. RICHARDS, of Purdy & Henderson, Inc., Civil Engineers, New York, N. Y.

GRENVILLE T. SNELLING, Architect, formerly Instructor in Architectural Engineering, Columbia University.

A. P. STRADLING, Manager, Philadelphia Suburban Underwriters' Association.

W. H. TIMBIE, Head of Applied Science Department, Wentworth Institute.

CHARLES P. WARREN, Assistant Professor of Architecture, Columbia University.

PREFACE TO SIXTEENTH EDITION

The changes in the fifteenth edition, published in 1908, consisted principally of the rewriting of the two chapters on Fireproofing of Buildings and Reinforced Concrete.

In 1912 the undersigned was asked to undertake the revision of the entire book with the cooperation of a corps of Associate Editors, each highly qualified to render the necessary assistance in matters pertaining to his own work. On account of the comprehensive nature of the contents of the Pocket-Book, the many recent changes and rapid developments in different fields of architectural construction, and the consequent effect of such changes on the interrelated subjects treated, the Editor-in-Chief decided to rewrite and reset the entire book. After more than three years of arduous labor, in which the Associate Editors and many other contributors have most ably and generously assisted, the New Kidder is about to be published.

It was decided to retain Mr. Kidder's original arrangement of the subject-matter which is divided into three Parts, Part I dealing with practical applications of Arithmetic, Geometry and Trigonometry, Part II with the Materials of Construction and the Strength and Stability of Structures, and Part III with miscellaneous useful information for architects and builders. Each of the twenty-nine chapters of Part II, however, has the name of the Associate Editor who revised or rewrote it printed with the chapter-caption. Part I has been carefully checked and much of the matter rearranged. The twenty-eight chapters of Part II have been rewritten and one new chapter has been added on Reinforced-Concrete Mill and Factory-Construction. Part III has been largely rewritten and all subjects retained have been thoroughly revised. To this part, also, much new matter has been added, such as extended tables of Specific Gravities and Weights of Substances, Architectural Acoustics, Waterproofing for Foundations, the Quantity System of Estimating, the Standard Documents of the American Institute of Architects, Educational Societies of the World and extended lists of Architectural Schools, Books and Periodicals.

The Editor-in-Chief has, with very few exceptions, personally checked on every page of manuscript, galley-proof and page-proof the equations, formulas, computations and problems, and has read or examined carefully every word, figure and illustration, every detail of syntax, paragraphing, punctuation and typography, and every arrangement of tables, captions, classifications, notation, Table of Contents and Index.

He is responsible for many changes in the form of presentation of data which it is hoped will add to the Pocket-Book still more of that efficiency and practical helpfulness for which it has been so long noted. Some of these changes may be briefly mentioned. The text has been entirely reset; the type, while slightly smaller, is clearer and has the lines and paragraphs separated by wide leads; a special type is used for the tables; the paragraphing is revised throughout and every paragraph has a black-face type caption descriptive of the subject-matter; words in italics or with quotation-marks are seldom used, words in small caps taking their place; every chapter is divided into numbered chapter-subdivisions which are briefly descriptive of the classified matter; the number of cross-

references is largely increased and the page-numbers of such references are almost always added; many tables and diagrams which in the former editions read lengthwise of the page have been reset or reengraved to read across the page for greater convenience; the number of illustrations has been largely increased, many old cuts reused have been reengraved, and some diagrams printed with lines of different colors to make the demonstrations clearer; a descriptive caption has been added to every illustration; the abbreviations Chap. I, Chap. II, etc., have been printed with each page-caption of the left-hand pages, thus avoiding the necessity of referring to the Table of Contents to locate any particular chapter.

The Editor-in-Chief decided to change some of the unit stresses, especially those for the different woods, and in some cases to recommend more conservative values, and he believes that results based upon such stresses conform to the best engineering practice. This change necessitated the revision of many tables and problems throughout the book which had to be entirely recalculated. Numerous practical problems with complete solutions have been added. The derivation of many of the formulas used has been explained, either in the body of the text or in extended foot-notes, for those who wish to understand as well as to use such formulas, and numerous cross-references accompanying them enable the reader to use the Pocket-Book as a textbook for certain parts of the mechanics of materials as well as a handbook for office work. The tables of the properties of structural shapes, of safe loads for columns, beams and girders, etc., have been revised and numerous new tables added. The Editor has found that it is the consensus of opinion among architects that the insertion of these tables is a great convenience and for their ordinary office work condenses into one handy volume much of the essential data of several manufacturers' handbooks.

The difficulty of securing a unity of treatment and of avoiding repetitions and contradictions in a book of reference the data of which covers so many subjects and is written by so many contributors has been fully realized; but it is believed that in these respects the New Kidder is reasonably successful and will meet with the approval of all who use it.

Acknowledgments and thanks are due the Associate Editors for their hearty cooperation and generous contributions of the time and labor taken from their professional work. Acknowledgment is made, also, of the valuable assistance of all others who have furnished new or revised old data, and of many helpful suggestions from Mrs. F. E. Kidder and from the publishers.

The Editor-in-Chief expresses the hope that for the architects and builders of this country the new Pocket-Book will continue to be, as Mr. Kidder expressed it in his preface to the first edition in 1884, "a compendium of practical facts, rules and tables presented in a form as convenient for application as possible, and as reliable as our present knowledge will permit;" and also, in its present extension and fuller development, a work which will lead to a still clearer understanding of the essential principles of sound architectural construction.

THOMAS NOLAN.

PHILADELPHIA, September, 1915.

PREFACE TO FOURTEENTH EDITION

It is now nearly twenty years since the author, then quite a young man, completed the first edition of this work, which, although containing but 586 pages, had required about three years for its preparation. At that time the author thought he had covered all of those practical details relating to the planning and construction of buildings, with which the architect was concerned, tolerably well, and it would appear as though the purchasers of the book thought so too, but as the years have come and gone, so many and such great improvements have taken place in the building world, so many articles invented, new methods of construction developed, higher standards established, that the present edition, although containing nearly three times as many pages, is perhaps not more complete, for the times, than was the first edition.

When preparing the first edition, it was the aim of the author to give to architects and builders a handbook which should be, in its field, as useful and reliable as Trautwine's had been to civil engineers; and with that object constantly in view, the book has been revised from time to time to meet the changed conditions in building construction and equipment.

About three years ago it was thought, by the publishers and the author, that a thorough and complete revision of the book should be undertaken, and although the re-writing of a work of this character, even with the thirteenth edition to work from, involved many months of close and constant application, the utilization of those hours which one ordinarily takes for recreation, and at the best more or less interruption to his regular business, and consequent reduction in income, the writer undertook to prepare a work of a still wider scope, and which should be thoroughly up-to-date in every particular, or at least as far as is practicable, in a work requiring a period of three years in its preparation, and from that time to this he has spared no labor or expense to make the book as useful and complete as he possibly could, without making it too bulky.

In this revision the author has had in view:

1st. A reference-book which should contain some information on every subject (except design) likely to come before an architect, structural engineer, draughtsman, or master-builder, including data for estimating the approximate cost.

2d. To as thoroughly cover the subject of architectural engineering as is practicable in a handbook.

3d. To present all information in as simple and convenient a form for immediate application as is consistent with accuracy. To this end a great many new tables, arranged and computed by the author, have been inserted.

At the time the first edition was written, the term "Architectural Engineering" had not been used in its present application, and the term "Structural Engineering," when used, referred almost exclusively to bridge work.

To-day, structural and architectural engineers are concerned almost exclusively with building construction, and their work is more closely allied to that of the architect than to that of the civil engineer; hence the author has had in mind the needs of the structural engineer and draughtsman as well as those of the architect and builder, and the book should be of nearly equal value to both.

Where it was impossible, for lack of space, to go extensively into any subject, references to other books or sources of information have been given, so that in this way the book may serve as a general index to the many lines of work, materials, and manufactured products entering into the planning, construction, and equipment of buildings.

To attain the objects in view, it has been necessary to add considerably to the number of pages, but as experience has shown that the book is used principally at the desk or draughting-table, and is seldom carried in the pocket, it is believed that the convenience of having everything in one book will more than offset any disadvantage resulting from increase in bulk.

Nearly the entire book has been re-written, and great pains have been taken to furnish reliable data. A large number of experts in various lines have assisted the author, as is manifest by the foot-notes and references. To all of such, and to the many authors of technical works, and to the publishers of technical journals, who have kindly consented to the use of cuts and data, the author takes pleasure in acknowledging his indebtedness. Also to Mr. E. S. Hand, of New York, who, for many years, has rendered material assistance in collecting data along the line of manufactured products.

The names and addresses of manufacturers have been given solely for the convenience of the users of the book, and not for any pecuniary considerations; in fact, if money considerations had solely appealed to the writer, this book would never have been re-written, because a technical work of this character can never adequately compensate, in money, for the time, labor, and thought required in its preparation. The many words of appreciation which have come to the author from hundreds of those who have found the book useful have been a great stimulus to further increase its usefulness.

As in the former prefaces, the author requests that any one discovering errors in the work or who may have any suggestions looking to the further improvement of the book, will communicate the same to him, that the book may be made as complete and reliable as possible.

Finally, the author desires to acknowledge his indebtedness to the publishers, who have heartily seconded his efforts in every particular, and who have spared no pains or expense to make a perfect handbook.

F. E. KIDDER.

DENVER, COLO., July 18th, 1904.

CONTENTS

PART I

PRACTICAL ARITHMETIC, GEOMETRY AND TRIGONOMETRY

	Page
Arithmetical Signs and Characters	3
Involution	3
Evolution, Square and Cube Root, Rules and Tables	4
Weights and Measures	25
The Metric System	30
Metric Conversion Tables	32
Scripture and Ancient Measures and Weights	34

STRENGTH OF MATERIALS AND STABILITY OF STRUCTURES

Introduction	121
Explanation of Notation and Symbols	122

CHAPTER I

EXPLANATION OF TERMS USED IN ARCHITECTURAL ENGINEERING

BY

THOMAS NOLAN

PROFESSOR OF ARCHITECTURAL CONSTRUCTION, UNIVERSITY OF PENNSYLVANIA

1. Definitions of Some of the Terms Used in Mechanics of Materials.	124
2. Classifications of the Principal Stresses Caused in Bodies by External Forces	127

CHAPTER II

FOUNDATIONS

BY

DANIEL E. MORAN

MEMBER OF AMERICAN SOCIETY OF CIVIL ENGINEERS

1. Definition of the Word and Terms Used	129
2. General Requirements	129
3. Geological Considerations	130

PAGE
4. Composition and Classification of Rocks 130
5. Geology of Earthy Material 132
6. Materials Composing Foundation-Beds 134
7. Characteristics of the Materials of Foundation-Beds 135
8. Allowable Loads on Materials of Foundation-Beds 140
9. Unit Loads on Foundation-Beds Allowed by Building Codes 142
10. Investigation of the Site 142
11. Loading-Tests 145
12. Topographical and Special Conditions 146
13. Loads Coming on the Footings 148
14. Assumed Loads Specified by Building Codes 151
15. Proportioning Supporting Areas for Equal Settlement 152
16. Determining the Supporting Areas 160
17. Offset Footings 163
18. The Use of Cantilevers in Foundations 165
19. Stresses in Footing Courses 169
20. Methods of Calculating Bending-Stresses in Wall-Footings 172
21. Bending Moments in Footings of Columns and Piers 176
22. Design of the Footings 178
23. Steel Grillages in Foundations 181
24. Reinforced-Concrete Footings 186
25. Timber Footings for Temporary Buildings 186
26. General Conditions Affecting Foundations and Footings 188
27. Wooden-Pile Foundations 188
28. Concrete-Pile Foundations 196
29. Foundation Piers and Foundation Walls 200
30. Methods of Excavating for Foundations 200
31. Protection of Adjoining Structures 214

CHAPTER III

MASONRY WALLS. FOOTINGS FOR LIGHT BUILDINGS. CEMENTS AND CONCRETES

BY

THOMAS NOLAN

PROFESSOR OF ARCHITECTURAL CONSTRUCTION, UNIVERSITY OF PENNSYLVANIA

1. Footings for Light Buildings 223
2. Cellar Walls and Basement Walls 228
3. Walls of the Superstructure 229
4. Natural Cements 235
5. Artificial Cements 236
6. Concrete 240

CHAPTER IV

RETAINING-WALLS, BREAST-WALLS AND VAULT-WALLS

BY

GRENVILLE TEMPLE SNELLING

MEMBER OF AMERICAN INSTITUTE OF ARCHITECTS

1. Mechanical Principles Involved 252
2. Retaining-Walls 255

5. Graphical Determination of the Stability of Arches 311

CHAPTER IX

REACTIONS AND BENDING MOMENTS FOR BEAMS

BY

CHARLES P. WARREN

ASSISTANT PROFESSOR OF ARCHITECTURE, COLUMBIA UNIVERSITY

	PAGE
1. Reactions for Beams	322
2. Bending Moments in Beams	324
3. Bending Moments in Beams for Different Kinds of Loading	325
4. Graphic Method for Determining Bending Moments in Beams	328

CHAPTER X

PROPERTIES OF STRUCTURAL SHAPES, MOMENT OF INERTIA, MOMENT OF RESISTANCE, SECTION-MODULUS AND RADIUS OF GYRATION

BY

CHARLES P. WARREN

ASSISTANT PROFESSOR OF ARCHITECTURE, COLUMBIA UNIVERSITY

1. The Properties of Cross-Sections	332
2. Areas, Moments of Inertia, Section-Moduli and Radii of Gyration of Elementary Sections	334
3. Transferring Moments of Inertia to Other Parallel Axes	338
4. Moments of Inertia of Compound Sections	339
5. Radii of Gyration of Compound Sections	344
6. Dimensions, Moments of Inertia, Radii of Gyration and Section-Moduli of Standard Structural Shapes	352

CHAPTER XI

RESISTANCE TO TENSION. PROPERTIES OF IRON AND STEEL

BY

HERMAN CLAUDE BERRY

PROFESSOR OF MATERIALS OF CONSTRUCTION, UNIVERSITY OF PENNSYLVANIA

1. Definitions, Working Stresses and Examples	373
2. Wrought Iron	377
3. Cast Iron	379
4. Steel	380
5. Standard Specifications for Structural Steel for Buildings	383
6. Tension-Members	385
7. Wire	400
8. Wire Rope	404
9. Cotton, Hemp and Manila Rope	406
10. Chains	408

CHAPTER XII

RESISTANCE TO SHEAR. RIVETED JOINTS. PINS AND BOLTS

BY

HERMAN CLAUDE BERRY

PROFESSOR OF MATERIALS OF CONSTRUCTION, UNIVERSITY OF PENNSYLVANIA

	PAGE
1. Shear	411
2. Riveted Joints	413
3. Strength of Pins in Trusses	423
4. Strength of Bolts in Wooden Trusses and Girders	429

CHAPTER XIII

BEARING-PLATES AND BASES FOR COLUMNS, BEAMS AND GIRDERS. BRACKETS ON CAST-IRON COLUMNS

BY

HERMAN CLAUDE BERRY

PROFESSOR OF MATERIALS OF CONSTRUCTION, UNIVERSITY OF PENNSYLVANIA

1. Bearing-Plates and Bases	440
2. Bearing-Brackets on Cast-Iron Columns	445

CHAPTER XIV

STRENGTH OF COLUMNS, POSTS AND STRUTS

BY

CHARLES P. WARREN

ASSISTANT PROFESSOR OF ARCHITECTURE, COLUMBIA UNIVERSITY

1. General Principles and Definitions	448
2. Strength of Short Wooden Columns	448
3. Strength of Wooden Columns or Struts Over Ten Diameters in Length. Formulas	449
4. Tables of Safe Loads for Wooden Columns	450
5. Eccentric Loading of Wooden Columns	453
6. Metal Caps and Bolsters for Wooden Columns	454
7. Crushing of Wood Perpendicular to the Grain	454
8. Cast-Iron Columns	455
9. Design of Cast-Iron Columns	456
10. Strength of Cast-Iron Columns. Formulas	459
11. Tables of Safe Loads for Cast-Iron Columns. Examples	461
12. Types, Forms and Connections of Steel Columns	467
13. Strength of Steel Columns. Formulas	480
14. Design of Steel Columns. Examples	482
15. Eccentric Loading of Steel Columns	485
16. Tables of Safe Loads for Steel Columns	488

CHAPTER XV

STRENGTH OF BEAMS AND BEAM GIRDERS. FRAMING AND CONNECTING STEEL BEAMS

BY

CHARLES P. WARREN

ASSISTANT PROFESSOR OF ARCHITECTURE, COLUMBIA UNIVERSITY

	PAGE
1. General Principles of the Flexure of Beams	555
2. Formulas for Safe Loads for Beams for Different Conditions of Loading and Support	558
3. Steel Beams and Girders	564
4. Tables of Safe Loads for Steel Beams and Girders. Examples	570
5. Framing and Connecting Steel Beams and Girders	612

CHAPTER XVI

STRENGTH OF CAST-IRON LINTELS AND WOODEN BEAMS

BY

F. H. KINDL

CORRESPONDING MEMBER AMERICAN INSTITUTE OF ARCHITECTS

1. Cast-Iron Lintels	620
2. Sections, Stresses, Buckling and Deflection of Wooden Beams	627
3. Constants and Coefficients for Beams	628
4. Flexural Strengths of Wooden Beams	629
5. Application of Formulas for Flexural Strengths of Wooden Beams	631
6. Flexural Strengths of Beams	633
7. Tables for Strength and Stiffness of Wooden Beams	635
8. Working Unit Stresses for Woods	647
9. Working Unit Stresses for Woods. Taken from Building Laws	647

CHAPTER XVII

STRENGTH OF BUILT-UP, FLITCHED AND TRUSSED WOODEN GIRDERS

BY

F. H. KINDL

CORRESPONDING MEMBER AMERICAN INSTITUTE OF ARCHITECTS

1. Built-Up Wooden Girders	652
2. Flitched Beams or Flitch-Plate Girders	655
3. Trussed Beams and Girders	656

CHAPTER XVIII

STIFFNESS AND DEFLECTION OF BEAMS

BY

CHARLES P. WARREN

ASSISTANT PROFESSOR OF ARCHITECTURE, COLUMBIA UNIVERSITY

1. General Principles of the Deflection of Beams	663
2. Formulas for Loads, Based upon the Stiffness of Beams	665
3. Relative Stiffness of Beams	666
4. Cylindrical Beams	667
5. Safe Loads for Wooden Beams for a Given Deflection	667
6. Nominal and Standard Sizes of Wooden Beams	667

CHAPTER XIX

STRENGTH AND STIFFNESS OF CONTINUOUS GIRDERS

BY

CHARLES P. WARREN

ASSISTANT PROFESSOR OF ARCHITECTURE, COLUMBIA UNIVERSITY

PAGE

1. General Considerations 671
2. Supporting Forces or Reactions of Continuous Girders 671
3. Bending Moments of Continuous Girders 673
4. Deflection of Continuous Girders 674
5. Notes on Reactions, Strength and Stiffness of Continuous Girders . . 675
6. Formulas for the Strength and Stiffness of Continuous Girders . . . 676
7. Continuous Girders in Grillage Foundations 678

CHAPTER XX

RIVETED STEEL PLATE AND BOX GIRDERS

BY

CHARLES P. WARREN

ASSISTANT PROFESSOR OF ARCHITECTURE, COLUMBIA UNIVERSITY

1. General Notes on Plate and Box Girders 681
2. Details of Construction of Plate and Box Girders 682
3. Design of Plate and Box Girders 683
4. Explanation of Tables 688
5. Examples of Plate and Box Girders 688
6. Tables Used in the Design of Plate and Box Girders 702

CHAPTER XXI

STRENGTH AND STIFFNESS OF WOODEN FLOORS

BY

THOMAS NOLAN

PROFESSOR OF ARCHITECTURAL CONSTRUCTION, UNIVERSITY OF PENNSYLVANIA

1. Loads on Floors and Weights of Floor-Construction 718
2. Tables of Weights of Merchandise 721

PART I

PRACTICAL
ARITHMETIC, GEOMETRY AND TRIGONOMETRY

RULES, TABLES AND PROBLEMS

1. PRACTICAL ARITHMETIC

Mathematical Signs and Characters *

The following signs and characters are generally used to denote and abbreviate the several mathematical operations:

The sign = means equal to, or equality;

$-$ means minus or less, or subtraction;

$+$ means plus, or addition;

$\times$ means multiplied by, or multiplication;

$\div$ or / means divided by, or division;

^{2} } ^{3} } are indexes or powers, meaning that the number to which they are added is to be squared (^{2}) or cubed (^{3});

: is to } : : so is } : to } are signs of proportion;

$\sqrt{\ }$ is the RADICAL SIGN and means that the square root of the number before which it is placed is to be extracted;

$\sqrt[3]{\ }$ means that the cube root of the number before which it is placed is to be extracted;

—— the BAR indicates that all the numbers under it are to be taken together;

( ) the PARENTHESIS means that all the numbers between are to be taken as one quantity;

. means decimal parts; thus, 2.5 means $2\frac{5}{10}$, 0.46 means $\frac{46}{100}$.

° means degrees, ′ minutes and ″ seconds;

$\therefore$ means hence;

′ means feet;

″ means inches.

Involution

To Square a Number, multiply the number by itself, and the product will be the square; thus, the square of $18 = 18^2 = 18 \times 18 = 324$.

The Cube of a Number is the product obtained by multiplying the number by itself, and that product by the number again; thus, the cube of $14 = 14^3 = 14 \times 14 \times 14 = 2\,744$.

The Fourth Power of a Number is the product obtained by multiplying the number by itself four times; thus, the fourth power of $10 = 10^4 = 10 \times 10 \times 10 \times 10 = 10\,000$.

Evolution

Square Root. Rule for extracting the square root of a number:

(1) Divide the given number into periods of two figures each, commencing at the right if it is a whole number, and at the decimal point if there are decimals; thus, $\dot{1}0\dot{2}3\dot{6}.8\dot{1}2\dot{6}$.

(2) Find the largest square in the left-hand period, and place its root in the quotient; subtract the said square from the left-hand period, and to the remainder bring down the next period for a new dividend.

(3) Double the root already found, and annex one cipher for a trial-divisor; see how many times it will go in the dividend, and put the number in the quotient

* See, also, pages 122 and 123, Part II.

and also in place of the cipher in the divisor. Multiply this final divisor by the number in the quotient just found, subtract the product from the dividend, and to the remainder bring down the next period for a new dividend and proceed as before. If it should be found that the trial divisor cannot be contained in the dividend, bring down the next period for a new dividend, annex another cipher to the trial divisor, put a cipher in the quotient and proceed as before.

Example. 10236.8126 (101.17, the square root

$$
\begin{array}{rr}
 & 1 \\
201) & 0236 \\
 & 201 \\
2021) & 3581 \\
 & 2021 \\
20227) & 156026 \\
 & 141589 \\
 & 14437
\end{array}
$$

Cube Root. To extract the cube root of a number, point off the number from right to left into periods of three figures each, and, if there is a decimal, commence at the decimal point and point off into periods, going both ways.

Ascertain the highest root of the first period, and place it to the right of the number, as in long division; cube the root thus found and subtract from the first period; to the remainder annex the next period; square the root already found, multiply by three and annex two ciphers for the trial divisor. Find how many times this trial divisor is contained in the dividend and write the result in the root.

Add together the trial divisor, three times the product of the first figure of the root by the second with one cipher annexed, and the square of the second figure in the root: multiply the sum by the last figure in the root, and subtract from the dividend; to the remainder annex the next period and proceed as before.

When the trial divisor is greater than the dividend, write a cipher in the root, annex the next period to the dividend and proceed as before.

Example. Required, the cube root of 493039 or $\sqrt[3]{493039}$

$$
\begin{array}{rr|l}
 & & 493039\text{(79, the cube root} \\
7\times7\times7 = & & 343 \\
7\times7\times3 = & 14700 & 150039 \\
7\times9\times3 = & 1890 & \\
9\times9 = & 81 & \\
 & 16671 & 150039
\end{array}
$$

Example. Required, the cube root of 403583.419 or $\sqrt[3]{403583.419}$

$$
\begin{array}{rr|l}
 & & 403583.419\text{(73.9, the cube root} \\
7\times7\times7 = & & 343 \\
7\times7\times3 = & 14700 & 60583 \\
7\times3\times3 = & 630 & \\
3\times3 = & 9 & \\
 & 15339 & 46017 \\
73\times73\times3 = & 1598700 & 14566419 \\
73\times9\times3 = & 19710 & \\
9\times9 = & 81 & \\
 & 1618491 & 14566419
\end{array}
$$

Example. Required, the cube root of 158252.632929 or $\sqrt[3]{158252.632929}$

$$
\begin{array}{rr|l}
 & & 15\dot{8}25\dot{2}.63\dot{2}92\dot{9}(54.09, \text{ the cube root} \\
 & 5 \times 5 \times 5 = & 125 \\
\hline
 & 5 \times 5 \times 3 = 7500 & 33252 \\
 & 5 \times 4 \times 3 = 600 & \\
 & 4 \times 4 = 16 & \\
\cline{2-2}
 & 8116 & 32464 \\
\hline
540 \times 540 \times 3 = & 87480000 & 788632929 \\
540 \times \quad 9 \times 3 = & 145800 & \\
9 \times 9 = & 81 & \\
\cline{2-2}
 & 87625881 & 788632929 \\
\hline
\end{array}
$$

TABLES

OF

SQUARES, CUBES, SQUARE ROOTS, CUBE ROOTS AND RECIPROCALS

From 1 to 1054

The following table, taken from Searle's Field Engineering, will be found of great convenience in finding the square, cube, square root, cube root and reciprocal of any number from 1 to 1054. The reciprocal of a number is the quotient obtained by dividing 1 by the number. Thus, the reciprocal of 8 is $1 \div 8 = 0.125$.

No.	Squares	Cubes	Square roots	Cube roots	Reciprocals
1	1	1	1.0000000	1.0000000	1.000000000

2. WEIGHTS AND MEASURES

Measures of Length

12 inches	= 1 foot					
3 feet	= 1 yard	=	36 inches			
5½ yards	= 1 rod	=	198 inches =	16½ feet		
40 rods	= 1 furlong	=	7 920 inches =	660 feet =	220 yards	
8 furlongs	= 1 mile	=	63 360 inches =	5 280 feet =	1 760 yards =	320 rods
1 yard	= 0.0005682 of a mile					

Gunter's Chain

7.92 inches = 1 link
100 links = 1 chain = 4 rods = 66 feet
80 chains = 1 mile

Ropes and Cables

6 feet = 1 fathom   120 fathoms = 1 cable's length

Nautical Measures

A nautical or sea-mile is the length of a minute of longitude of the earth at the equator at the level of the sea. It is assumed that 6086.07 ft = 1.152664 statute or land-miles by the United States Coast Survey.

3 nautical miles = 1 league

Miscellaneous Measures

1 palm = 3 inches	1 span = 9 inches
1 hand = 4 inches	1 meter = 3.2809 feet

Measures of Surface

144 square inches	= 1 square foot	
9 square feet	= 1 square yard	= 1 296 square inches
100 square feet	= 1 square (architects' measure)	

Land Measure

30¼ square yards	= 1 square rod	
40 square rods	= 1 square rood	= 1 210 square yards
4 square roods } 10 square chains }	= 1 acre	= 4 840 square yards
	= 160 square rods	
640 acres }	= 1 square mile	= 3 097 600 square yards = }
102 400 square rods }	= 2 560 square roods	
208.71 feet square	= 1 acre	

A SECTION of land is a square mile, and a QUARTER-SECTION is 160 acres

Measures of Volume

1 gallon, liquid measure = 231 cubic inches, and contains 8.339 avoirdupois pounds of distilled water at 39.8° F., or 58 333 grains

1 cubic foot contains 7.48 liquid gallons, or 6.428 dry gallons

1 gallon, dry measure = 268.8 cubic inches

1 bushel (Winchester) contains 2150.42 cubic inches, or 77.627 pounds distilled water at 39.8° F.

A heaped bushel contains 2747.715 cubic inches

Dry Measure

2 pints	= 1 quart	=		67.2 cubic inches
4 quarts	= 1 gallon	= 8 pints =		268.8 cubic inches
2 gallons	= 1 peck	= 16 pints =	8 quarts =	537.6 cubic inches
4 pecks	= 1 bushel	= 64 pints =	32 quarts =	8 gallons
	= 2150.42 cubic inches			

1 cord of wood = 128 cubic feet

Liquid Measure

4 gills	= 1 pint	= 16 fluid ounces
2 pints	= 1 quart	= 8 gills = 32 fluid ounces
4 quarts	= 1 gallon	= 32 gills = 8 pints = 128 fluid ounces

In the United States and Great Britain 1 barrel of wine or brandy = 31½ gallons, and contains 4.211 cubic feet.

A hogshead is 63 gallons, but this term is often applied to casks of various capacities.

Cubic Measure

1728 cubic inches	= 1 cubic foot
27 cubic feet	= 1 cubic yard

In MEASURING WOOD, a pile of wood cut 4 feet long, piled 4 feet high, and 8 feet on the ground, making 128 cubic feet, is called a CORD.

16 cubic feet make one cord-foot.

A PERCH OF STONE is nominally 16½ feet long, 1 foot high and 1½ feet thick, and contains 23¾ cubic feet.

A perch of stone is, however, often computed differently in different localities; thus, in most if not all of the States and Territories west of the Mississippi, stone-masons figure rubble by the perch of 16½ cubic feet. In Philadelphia, 22 cubic feet are called a perch. In Chicago, stone is measured by the cord of 100 cubic feet.

A TON of shipping is 42 cubic feet in Great Britain and 40 cubic feet in the United States.

Fluid Measure

60 minims	= 1 fluid drachm
8 fluid drachms	= 1 ounce
16 ounces	= 1 pint
8 pints	= 1 gallon

Miscellaneous Measures

Butt of Sherry	= 108 gallons	Puncheon of Brandy	= 110 to 120 gallons
Pipe of Port	= 115 gallons	Puncheon of Rum	= 100 to 110 gallons
Butt of Malaga	= 105 gallons	Hogshead of Brandy	= 55 to 60 gallons
Puncheon of Scotch Whiskey,	= 110 to 130 gallons	Hogshead of Claret	= 46 gallons

Measures of Weight

The standard AVOIRDUPOIS POUND is the weight of 27.7015 cubic inches of distilled water weighed in air at 39.83° F., with the barometer at 30 inches. It contains 7 000 grains. One pound avoirdupois = 1.2153 pounds troy.

Avoirdupois, or Ordinary Commercial Weight

1 drachm	= 27.343 grains	
16 drachms	= 1 ounce	(oz)
16 ounces	= 1 pound	(lb)
100 pounds	= 1 hundredweight	(cwt)
20 hundredweight	= 1 ton	

In collecting duties upon foreign goods at the United States custom-houses, and also in freighting coal and selling it by wholesale,

28 pounds	= 1 quarter
4 quarters, or 112 pounds	= 1 hundredweight
20 hundredweight	= 1 long ton = 2 240 pounds
A stone	= 14 pounds
A quintal	= 100 pounds

The following measures are sanctioned by custom or law: 1 bushel = 1.244 cubic feet or 1¼ cubic feet, nearly.

32 pounds of oats	= 1 bushel
45 pounds of Timothy-seed	= 1 bushel
48 pounds of barley	= 1 bushel
56 pounds of rye	= 1 bushel
56 pounds of Indian corn	= 1 bushel
50 pounds of Indian meal	= 1 bushel
60 pounds of wheat	= 1 bushel
60 pounds of clover-seed	= 1 bushel
60 pounds of potatoes	= 1 bushel

56 pounds of butter	=	1 firkin
100 pounds of meal or flour	=	1 sack
100 pounds of grain or flour	=	1 cental
100 pounds of dry fish	=	1 quintal
100 pounds of nails	=	1 cask
196 pounds of flour	=	1 barrel
200 pounds of beef or pork	=	1 barrel
80 pounds of lime	=	1 bushel

Troy Weight

Used in Weighing Gold or Silver

24 grains	=	1 pennyweight	(pwt)
20 pennyweights	=	1 ounce	(oz)
12 ounces	=	1 pound	(lb)

A CARAT of the jewelers, for precious stones, is, in the United States, 3.2 grains, but it varies according to different authorities. In London, 3.17 grains, in Paris, 3.18 grains are divided into 4 jewelers' grains. The international carat is 3.168 grains or 200 milligrams. In troy, apothecaries' and avoirdupois weights, the grain is the same, 1 pound troy being equal to 0.82286 pound avoirdupois.

Apothecaries' Weight

Used in Compounding Medicines and in Putting Up Medical Prescriptions

20 grains (gr)	= 1 scruple (℈)	8 drachms	= 1 ounce (oz)
3 scruples	= 1 drachm (ʒ)	12 ounces	= 1 pound (lb)

Measures of Value

United States Standard

10 mills	= 1 cent	10 dimes	= 1 dollar
10 cents	= 1 dime	10 dollars	= 1 eagle

The STANDARD of gold and silver is 900 parts of pure metal and 100 of alloy in 1 000 parts of coin.

The FINENESS expresses the quantity of pure metal in 1 000 parts.

The REMEDY OF THE MINT is the allowance for deviation from the exact standard fineness and weight of coins.

Weights of Coins

Double eagle	=	516	troy grains
Eagle	=	258	troy grains
Dollar (gold)	=	25.8	troy grains
Dollar (silver)	=	412.5	troy grains
Half-dollar	=	192	troy grains
5-cent piece (nickel)	=	77.16	troy grains
3-cent piece (nickel)	=	30	troy grains
Cent (bronze)	=	48	troy grains

Measures of Time

60 seconds = 1 minute	365 days = 1 common year
60 minutes = 1 hour	366 days = 1 leap-year
24 hours = 1 day	

A SOLAR DAY is measured by the rotation of the earth upon its axis, with respect to the sun.

In ASTRONOMICAL COMPUTATIONS and in NAUTICAL TIME the day commences at noon, and in the former it is counted throughout the 24 hours.

In CIVIL COMPUTATIONS the day commences at midnight, and is divided into two parts of 12 hours each.

A SOLAR YEAR is the time in which the earth makes one revolution around the sun. Its average time, called the MEAN SOLAR YEAR, is 365 days, 5 hours, 48 minutes and 49.7 seconds, or nearly 365¼ days.

A MEAN LUNAR MONTH, or LUNATION of the moon, is 29 days, 12 hours, 44 minutes, 2 seconds and 5.24 thirds. It is equal, on the average, to 29.53 days.

The Calendar, Old and New Style

The JULIAN Calendar was established by Julius Cæsar, 44 B.C., and by it one day was inserted in every fourth year. This was the same thing as assuming that the length of the solar year was 365 days and 6 hours, instead of the value given above, thus introducing an accumulative error of 11 minutes and 12 seconds every year. This calendar was adopted by the church in 325 A.D., at the Council of Nice. In the year 1582 the annual error of 11 minutes and 12 seconds had amounted to 10 days, which, by order of Pope Gregory XIII, was suppressed in the calendar, and the 5th of October reckoned as the 15th. To prevent the repetition of this error, it was decided to leave out three of the inserted days every 400 years, and to make this omission in the years which are not exactly divisible by 400. Thus, of the years 1700, 1800, 1900 and 2000, all of which are leap-years according to the Julian Calendar, only the last is a leap-year according to the REFORMED or GREGORIAN Calendar. This Reformed Calendar was not adopted by England until 1752, when 11 days were omitted from the calendar. The two calendars are now often called the OLD STYLE and the NEW STYLE. The latter style is now adopted in every Christian country except Russia.

Circular and Angular Measures

USED FOR MEASURING ANGLES AND ARCS, AND FOR DETERMINING LATITUDE AND LONGITUDE

60 seconds (″)	= 1 minute	(′)
60 minutes	= 1 degree	(°)
360 degrees	= 1 circumference	(C)

The SECOND is usually subdivided into tenths and hundredths.

A MINUTE of the circumference of the earth is a geographical mile.

The DEGREES of the earth's circumference on a meridian average 69.16 common miles.

The Metric System

The METRIC SYSTEM is a system of weights and measures based upon a unit called a METER.

The METER was intended to be one ten-millionth part of the distance from the equator to either pole, measured on the earth's surface at the level of the sea.

The NAMES of derived metric denominations are formed by prefixing to the name of the primary unit of measure:

Milli, a thousandth	Hecto, one hundred
Centi, a hundredth	Kilo, a thousand
Deci, a tenth	Myria, ten thousand
Deca, ten	

This system, first adopted by France, has been extensively adopted by other countries, and is much used in the sciences and the arts. It was legalized in 1866 by Congress to be used in the United States, and is already employed by the Coast Survey, and, to some extent, by the Mint and the General Post-Office.

Linear Measures

The METER is the primary unit of lengths.

10 millimeters (mm)	= 1 centimeter (cm)	= 0.3937 inch
10 centimeters	= 1 decimeter (dm)	= 3.937 inches
10 decimeters	= 1 METER (m)	= 39.37 inches
10 meters	= 1 decameter	= 393.37 inches
10 decameters	= 1 hectometer	= 328 feet 1 inch
10 hectometers	= 1 KILOMETER (km)	= 0.62137 mile
10 kilometers	= 1 myriameter	= 6.2137 miles

The METER is used in ordinary measurements; the CENTIMETER, or MILLIMETER, in reckoning very small distances; and the KILOMETER, for roads or great distances.

A CENTIMETER is about 3/8 of an inch; a METER is about 3 feet 3 3/8 inches; a KILOMETER is about 200 rods, or 5/8 of a mile. (See page 33.)

Measures of Surface

The SQUARE METER is the primary unit of ordinary surfaces.

The ARE, a square, each of whose sides is ten METERS, is the unit of land measures.

100 square millimeters (mm^2) = 1 square centimeter (cm^2) = 0.155 square inch
100 square centimeters = 1 square decimeter = 15.5 square inches
100 square decimeters = 1 square METER (m^2) = 1 550 square inches, or 1.196 square yards
100 centiares, or square meters = 1 ARE (a) = 119.6 square yards
100 ares = 1 hectare (ha) = 2.471 acres

A SQUARE METER, or one CENTIARE, is about 10 3/4 square feet, or 1 1/5 square yards, and a HECTARE is about 2 1/2 acres.

Cubic Measure

The CUBIC METER, or STERE, is the primary unit of a volume.

1 000 cubic millimeters (mm^3) = 1 cubic centimeter (cm^3) = 0.061 cubic inch
1 000 cubic centimeters = 1 cubic decimeter (dm^3) = 61.022 cubic inches
1 000 cubic decimeters = 1 cubic METER (m^3) = 35.314 cubic feet

The STERE is the name given to the cubic meter in measuring wood and timber. A tenth of a stere is a DECISTERE, and ten steres are a DECASTERE.

A CUBIC METER, or STERE, is about 1 1/3 cubic yards, or about 2 1/5 cord feet.

Liquid and Dry Measures

The LITER is the primary unit of measures of capacity, and is a cube, each of whose edges is a tenth of a meter in length.

The HECTOLITER is the unit in measuring large quantities of grain, fruits, roots and liquids.

10 milliliters (ml)	= 1 centiliter (cl)	= 0.338 fluid ounce
10 centiliters	= 1 deciliter	= 0.845 liquid gill
10 deciliters	= 1 LITER (l)	= 1.0567 liquid quarts
10 liters	= 1 decaliter	= 2.6417 gallons
10 decaliters	= 1 HECTOLITER (hl)	= 2 bushels, 3.35 pecks
10 hectoliters	= 1 kiloliter	= 28 bushels, 1½ pecks

A CENTILITER is about ⅓ of a fluid ounce; a LITER is about 1⅛ liquid quarts, or 9/10 of a dry quart; a HECTOLITER is about 2⅚ bushels; and a KILOLITER is one cubic meter, or stere.

Weights

The GRAM is the primary unit of weights, and is the weight in a vacuum of a cubic centimeter of distilled water at the temperature of 39.2° F.

10 milligrams (mg)	= 1 centigram (cg)	= 0.1543	troy grain
10 centigrams	= 1 decigram (dg)	= 1.543	troy grains
10 decigrams	= 1 GRAM (g)	= 15.432	troy grains
10 grams	= 1 decagram	= 0.3527	avoirdupois ounce
10 decagrams	= 1 hectogram	= 3.5274	avoirdupois ounces
10 hectograms	= 1 KILOGRAM (kg)	= 2.2046	avoirdupois pounds
10 kilograms	= 1 myriagram	= 22.046	avoirdupois pounds
10 myriagrams	= 1 quintal (q)	= 220.46	avoirdupois pounds
10 quintals	= 1 TONNEAU (t)	= 2204.6	avoirdupois pounds

1 kilogram per kilometer = 0.67195 pound per 1 000 feet
1 pound per thousand feet = 1.4882 kilograms per kilometer
1 kilogram per square millimeter = 1 423 pounds per square inch
1 pound per square inch = 0.000743 kilogram per square millimeter

The GRAM is used in weighing gold, jewels, letters and small quantities of things. The KILOGRAM, or, for brevity, KILO, is used by grocers; and the TONNEAU, or METRIC TON, is used in finding the weight of very heavy articles.

A GRAM is about 15½ grains troy; the KILO about 2⅕ pounds avoirdupois; and the METRIC TON, about 2 205 pounds.

A KILO is the weight of a liter of water at its greatest density; and the METRIC TON, of a cubic meter of water.

Metric numbers are written with the decimal point (.) at the right of the figures denoting the unit; thus the expression, 15 meters 3 centimeters, is written, 15.03 m.

When metric numbers are expressed by figures, the part of the expression at the left of the decimal point is read as the number of the unit, and the part at the right, if any, as a number of the lowest denomination indicated, or as a decimal part of the unit; thus, 46.525 m is read 46 meters and 525 millimeters, or 46 and 525 thousandths meters.

In writing and reading metric numbers, according as the scale is 10, 100 or 1 000, each denomination should be allowed one, two or three orders of figures.

Metric Conversion Table

The following metric conversion table has been compiled by C. W. Hunt, and is most convenient in dealing with metric weights and measures:

Millimeters × 0.03937	= inches
Millimeters ÷ 25.4	= inches
Centimeters × 0.3937	= inches
Centimeters ÷ 2.54	= inches
Meters × 39.37	= inches (Act of Congress)
Meters × 3.281	= feet
Meters × 1.094	= yards
Kilometers × 0.621	= miles
Kilometers ÷ 1.6093	= miles
Kilometers × 3280.7	= feet
Square millimeters × 0.0155	= square inches
Square millimeters ÷ 645.1	= square inches
Square centimeters × 0.155	= square inches
Square centimeters ÷ 6.451	= square inches
Square meters × 10.764	= square feet
Square kilometers × 247.1	= acres
Hectares × 2.471	= acres
Cubic centimeters ÷ 16.383	= cubic inches
Cubic centimeters ÷ 3.69	= fluid drachms (U.S. Pharmacopœia)
Cubic centimeters ÷ 29.57	= fluid ounce. (U.S. Pharmacopœia)
Cubic meters × 35.315	= cubic feet
Cubic meters × 1.308	= cubic yards
Cubic meters × 264.2	= gallons (231 cubic inches)
Liters × 61.022	= cubic inches. (Act of Congress)
Liters × 33.84	= fluid ounces. (U. S. Pharmacopœia)
Liters × 0.2642	= gallons (231 cubic inches)
Liters ÷ 3.78	= gallons (231 cubic inches)
Liters ÷ 28.316	= cubic feet
Hectoliters × 3.531	= cubic feet
Hectoliters × 2.84	= bushels (2 150.42 cubic inches)
Hectoliters × 0.131	= cubic yards
Hectoliters × 26.42	= gallons (231 cubic inches)
Grams × 15.432	= grains. (Act of Congress)
Grams × 981	= dynes
Grams (water) ÷ 29.57	= fluid ounces
Grams ÷ 28.35	= ounces avoirdupois
Grams per cubic centimeter ÷ 27.7	= pounds per cubic inch
Joule × 0.7373	= foot-pounds
Kilograms × 2.2046	= pounds
Kilograms × 35.3	= ounces avoirdupois
Kilograms ÷ 1102.3	= tons (2 000 pounds)
Kilograms per sq cm × 14.223	= pounds per square inch
Kilogrammeters × 7.233	= foot-pounds
Kilograms per meter × 0.672	= pounds per square foot
Kilograms per cubic meter × 0.062	= pounds per cubic foot
Kilograms per cheval-vapeur × 2.235	= pounds per horse-power
Kilowatts × 1.34	= horse-power
Watts ÷ 746	= horse-power
Watts × 0.7373	= foot-pounds per second
Calorie × 3.968	= British thermal units (B.T.U.)
Cheval-vapeur × 0.9863	= horse-power
(Centigrade × 1.8) + 32	= degrees Fahrenheit
Francs × 0.193	= dollars
Gravity, Paris	= 980.94 centimeter per second

Scripture and Ancient Measures and Weights

For meters, move the decimal point THREE figures forward.

Example. 8 3/16 inches = 207.96 millimeters = 20.796 centimeters = 2.0796 decimeters = 0.20796 meter.

3. GEOMETRY AND MENSURATION

Definitions

A POINT is that which has only position.

A PLANE is a surface in which, any two points being taken, the straight line joining them will be wholly in the surface.

A CURVED LINE is a line of which no part is straight (Fig. 1).

Fig. 1. Curved Line

Fig. 2. Parallel Lines

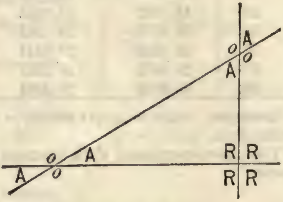

Fig. 3. Angles

PARALLEL LINES are such as are wholly in the same plane, and have the same direction (Fig. 2).

A BROKEN LINE is a line composed of a series of dashes; thus, —— —— ——.

An ANGLE is the opening between two lines meeting at a point, and is termed a RIGHT ANGLE when the two lines are perpendicular to each other, an ACUTE ANGLE when it is less or sharper than a right angle, and an OBTUSE ANGLE when it is greater than a right angle. Thus, in Fig. 3,

A A A A are ACUTE ANGLES,

o o o o are OBTUSE ANGLES and *R R R R* are RIGHT ANGLES.

Polygons

A POLYGON is a portion of a plane bounded by straight lines.

A TRIANGLE is a polygon of three sides.

A SCALENE TRIANGLE has none of its sides equal; an ISOSCELES TRIANGLE has two of its sides equal; an EQUILATERAL TRIANGLE has all three of its sides equal.

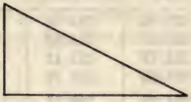

Fig. 4. Right-angled Triangle

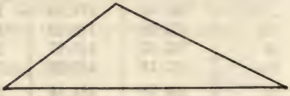

Fig. 5. Scalene Triangle

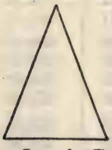

Fig. 6. Isosceles Triangle

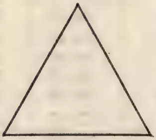

Fig. 7. Equilateral Triangle

A RIGHT-ANGLED TRIANGLE is one which has a right angle. The side opposite the right angle is called the HYPOTHENUSE; the side on which the triangle is supposed to stand is called its BASE and the other side, its ALTITUDE.

A QUADRILATERAL is a polygon of four sides.

Quadrilaterals are divided into classes, as follows: the TRAPEZIUM (Fig. 8), which has no two of its sides parallel; the TRAPEZOID (Fig. 9), which has two of its sides parallel; and the PARALLELOGRAM (Fig. 10), which is bounded by two pairs of parallel sides.

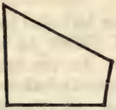

Fig. 8. Trapezium

Fig. 9. Trapezoid

Fig. 10. Parallelogram

A parallelogram whose sides are not equal and whose angles are not right angles is called a RHOMBOID (Fig. 11); when the sides are all equal, but the angles are not right angles, it is called a RHOMBUS (Fig. 12); and when the angles are right angles, it is called a RECTANGLE (Fig. 13). A rectangle, all of whose sides are equal, is called a SQUARE (Fig. 14). Polygons, all of whose sides are equal, are called REGULAR POLYGONS.

Fig. 11. Rhomboid

Fig. 12. Rhombus

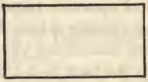

Fig. 13 Rectangle

Fig. 14. Square

Besides the square and equilateral triangles, there are: the PENTAGON (Fig. 15), which has five sides; the HEXAGON (Fig. 16), which has six sides; the HEPTAGON (Fig. 17), which has seven sides; and the OCTAGON (Fig. 18), which has eight sides.

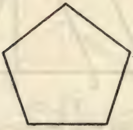

Fig. 15. Pentagon

Fig. 16. Hexagon

Fig. 17. Heptagon

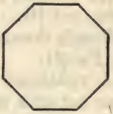

Fig. 18. Octagon

The ENNEAGON or NONAGON has nine sides; the DECAGON has ten sides; and the DODECAGON has twelve sides.

For all polygons, the side upon which it is supposed to stand is called its BASE; the perpendicular distance from the highest side or angle to the base (prolonged, if necessary) is called the ALTITUDE; and a line joining any two angles not adjacent is called a DIAGONAL.

A PERIMETER is the bounding line of a plane figure.

A CIRCLE is a portion of a plane bounded by a curve, all the points of which are equidistant from a point within, called the CENTER (Fig. 19).

The CIRCUMFERENCE is the curve which bounds the circle.

A RADIUS is any straight line drawn from the center to the circumference.

Any straight line drawn through the center to the circumference on each side is called a DIAMETER.

An ARC of a circle is any part of its circumference.

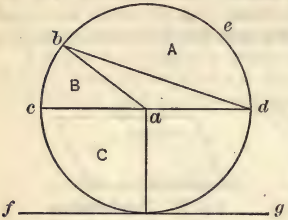

Fig. 19. Circle and Parts

A CHORD is any straight line joining two points of the circumference, as *bd*, Fig. 19.

A SEGMENT is a portion of the circle included between the arc and its chord, as *A*, Fig. 19.

A SECTOR is the space included between an arc and two radii drawn to its extremities, as *B*, Fig. 19. In the figure, *ab* is a radius, *cd* a diameter and *db* a chord SUBTENDING the arc *bed*. A TANGENT is a right line which in passing a curve touches without cutting it, as *fg*, Fig. 19.

Volumes

A PRISM is a volume whose ends are equal and parallel polygons and whose sides are parallelograms.

A prism is TRIANGULAR, RECTANGULAR, etc., according as its ends are TRIANGLES, RECTANGLES, etc.

A CUBE is a rectangular prism all of whose sides are squares.

A CYLINDER is a volume of uniform diameter, bounded by a curved surface and two equal and opposite parallel circles.

A PYRAMID is a volume whose base is a polygon and whose sides are triangles meeting in a point called the VERTEX. A pyramid is triangular, quadrangular, etc., according as its base is a triangle, quadrilateral, etc.

A CONE is a volume whose base is a circle, from which the remaining surface tapers uniformly to a point or vertex (Fig. 20).

A CONIC SECTION is the plane figure made by a plane cutting a cone.

An ELLIPSE is the section of a cone cut by a plane passing obliquely through both sides, as at *ab*, Fig. 21.

A PARABOLA is a section of a cone cut by a plane parallel to its side, as at *cd*.

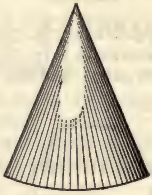

Fig. 20.
Cone

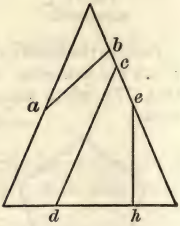

Fig. 21.
Cone with Section-lines

A HYPERBOLA is a section of a cone cut by a plane making a greater angle with the base than that made by the side of the cone, as at *eh*.

In the ellipse, the TRANSVERSE AXIS, OR LONG DIAMETER, is the longest line that can be drawn in it. The CONJUGATE AXIS, OR SHORT DIAMETER, is a line drawn through the center at right-angles to the long diameter.

A FRUSTUM OF A PYRAMID OR CONE is that which remains after cutting off the upper part of it by a plane parallel to the base.

A SPHERE is a volume bounded by a curved surface, all points of which are equidistant from a point within, called the center.

Mensuration treats of the measurement of lines, surfaces and volumes.

Rules

To compute the area of a square, a rectangle, a rhombus or a rhomboid.

Rule. Multiply the length by the breadth or height. Thus, in Figs. 22, 23 or 24, the area = $ab \times bc$.

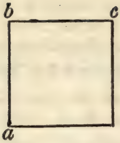

Fig. 22. Square

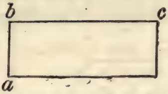

Fig. 23. Rectangle

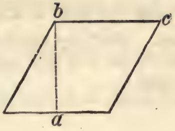

Fig. 24. Parallelogram

To compute the area of a triangle.

Rule. Multiply the base by the altitude and divide by 2. Thus, in Fig. 25, the area of $abc = \dfrac{ab \times cd}{2}$

To find the length of the hypothenuse of a right-angled triangle when both sides are known.

Rule. Square the length of each of the sides making the right angle, add their squares together and take the square root of their sum. Thus (Fig. 26), the length of $ac = 3$, and of $bc = 4$; then

$$ab = 3 \times 3 = 9 + (4 \times 4) = 9 + 16 = 25$$
$$\sqrt{25} = 5, \quad \text{or} \quad ab = 5$$

To find the length of the base or altitude of a right-angled triangle when the length of the hypothenuse and one side is known.

Rule. From the square of the length of the hypothenuse subtract the square of the length of the other side and take the square root of the remainder.

To find the area of a trapezium (Fig. 27).

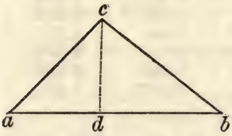

Fig. 25.
Scalene Triangle

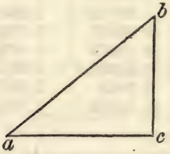

Fig. 26.
Right-angled Triangle

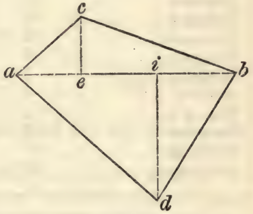

Fig. 27.
Trapezium

Rule. Multiply the diagonal by the sum of the two perpendiculars falling upon it from the opposite angles and divide the product by 2. Thus,

$$\frac{ab \times (ce + di)}{2} = \text{area}$$

To find the area of a trapezoid (Fig. 28).

Rule. Multiply the sum of the two parallel sides by the perpendicular distance between them and divide the product by 2.

To compute the area of an irregular polygon.

Rule. Divide the polygon into triangles by means of diagonal lines and then add together the areas of all the triangles, as *A*, *B* and *C* (Fig. 29).

To find the area of a regular polygon.

Rule. Multiply the length of a side by the perpendicular distance to the center (as *ao*, Fig. 30), multiply that product by the number of sides and divide the result by 2.

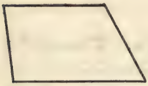

Fig. 28. Trapezoid

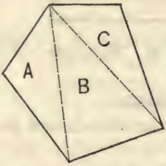

Fig. 29. Irregular Polygon

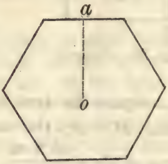

Fig. 30. Regular Polygon

To compute the area of a regular polygon when the length, only, of a side is given.

Rule. Multiply the square of the side by the multiplier opposite the name of the polygon in column *A* of the following table:

Table of Factors for Determining the Elements of Polygons

Name of polygon	Number of sides	*A* Factor for area	*B* Factor for radius of circumscribing circle	*C* Factor for length of the sides	*D* Factor for radius of inscribed circle
Triangle...........	3	0.433013	0.5773	1.732	0.2887
Tetragon...........	4	1	0.7071	1.4142	0.5
Pentagon...........	5	1.720477	0.8506	1.1756	0.6882
Hexagon...........	6	2.598076	1	1	0.866
Heptagon...........	7	3.633912	1.1524	0.8677	1.0383
Octagon...........	8	4.828427	1.3066	0.7653	1.2071
Nonagon...........	9	6.181824	1.4619	0.684	1.3737
Decagon...........	10	7.694209	1.618	0.618	1.5383
Undecagon.........	11	9.36564	1.7747	0.5634	1.7028
Dodecagon.........	12	11.196152	1.9319	0.5176	1.866

To compute the radius of a circle circumscribed about a regular polygon when the length, only, of a side is given.

Rule. Multiply the length of a side of the polygon by the number in column *B* of table.

Example. What is the radius of a circle that will contain a hexagon, the length of one side being 5 in?

Solution. $5 \times 1 = 5$ in.

To compute the length of a side of a regular polygon inscribed in a given circle, when the radius of the circle is given.

Rule. Multiply the radius of the circle by the number opposite the name of the polygon in column *C* of table.

Example. What is the length of the side of a pentagon contained in a circle 8 ft in diameter?

Solution. 8 ft diameter $\div 2 = 4$ ft radius; $4 \times 1.1756 = 4.7024$ ft.

To compute the length of a side of a regular polygon, when the radius of the inscribed circle is given.

Rule. Divide the radius of the inscribed circle by the number opposite the name of the polygon in column D of table.

To compute the radius of a circle that can be inscribed in a given regular polygon, when the length of a side is given.

Rule. Multiply the length of a side of the polygon by the number opposite the name of the polygon in column D.

Example. What is the radius of the circle that can be inscribed in an octagon, the length of one side being 6 in?

Solution. $6 \times 1.2071 = 7.2426$ in.

Circles

To compute the circumference of a circle.

Rule. Multiply the diameter by 3.1416. For many purposes, the multiplier $3\frac{1}{7}$ gives sufficiently accurate results.

Example. What is the circumference of a circle 7 in in diameter?

Solution. $7 \times 3.1416 = 21.9912$ in, or $7 \times 3\frac{1}{7} = 22$ in, the error in this last result being 0.0088 in.

To find the diameter of a circle when the circumference is given.

Rule. Divide the circumference by 3.1416, or for a very close approximate result, multiply by 7 and divide by 22.

To find the radius of an arc when the chord and rise or versed sine are given.

Rule. Square ONE-HALF the CHORD and the RISE; divide the sum of these squares by twice the rise; the result will be the radius.

Example. The length of the chord *ac*, Fig. 31, is 48 in, and the rise, *bo*, is 6 in. What is the radius of the arc?

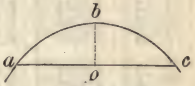

Fig. 31. Circular Arc, Chord and Rise

Solution. $\text{Radius} = \dfrac{oc^2 + bo^2}{2\,bo} = \dfrac{24^2 + 6^2}{12} = 51 \text{ in}$

To find the rise or versed sine of a circular arc, when the chord and radius are given.

Rule. Square the radius; also square one-half the chord; subtract the latter from the former and take the square root of the remainder. Subtract the result from the radius and the remainder will be the rise.

Example. A given arc has a radius of 51 in and a chord of 48 in. What is the rise?

Solution. $\text{Rise} = \text{radius} - \sqrt{\text{radius}^2 - \tfrac{1}{2}\text{chord}^2} = 51 - \sqrt{2\,601 - 576} = 51 - 45$
$= 6 \text{ in} = \text{rise}$

To compute the area of a circle.

Rule. Multiply the square of the diameter by 0.7854, or multiply the square of the radius of 3.1416.

Example. What is the area of a circle 10 in in diameter?

Solution. $10 \times 10 \times 0.7854 = 78.54$ sq in, or $5 \times 5 \times 3.1416 = 78.54$ sq in.

Tables of Areas and Circumferences of Circles

The following tables will be found very convenient for finding the circumferences and areas of circles.

Areas and Circumferences of Circles

For diameters from 1/10 to 100, advancing by tenths

Dia.	Area	Circum.	Dia.	Area	Circum.	Dia.	Area	Circum.

Circular Arcs

To find, by the following table, the length of a circular arc when its chord and height, or versed sine is given.

Rule. Divide the height by the chord; find in the column of heights the number equal to this quotient; take out the corresponding number from the column of lengths; and multiply this number by the given chord.

Example. The chord of an arc is 80 and its versed sine is 30. What is the length of the arc?

Solution. $30 \div 80 = 0.375$. The length of an arc for a height of 0.375 is, from table, 1.34063. $80 \times 1.34063 = 107.2504 =$ length of arc.

Table of Lengths of Circular Arcs whose Radius is 1

Rule. Knowing the measure of the circle and the measure of the arc in degrees, minutes and seconds; take from the table the lengths opposite the number of degrees, minutes and seconds in the arc, and multiply their sum by the radius of the circle.

Example. What is the length of an arc subtending an angle of $13° 27' 8''$ with a radius of 8 ft.

Solution.

$$
\begin{aligned}
\text{Length for } 13° &= 0.2268928 \\
27' &= 0.0078540 \\
8'' &= 0.0000388 \\
13°\ 27'\ 8'' &= 0.2347856 \\
& \quad \times 8 \\
\text{Length of arc} &= 1.8782848 \text{ ft}
\end{aligned}
$$

Lengths of Circular Arcs. Radius = 1

To compute the chord of an arc when the chord of half the arc and the versed sine are given.

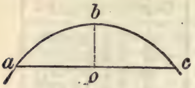

Fig. 32. Circular Arc, Chord and Rise

(The versed sine is the perpendicular *bo*, Fig. 32.)

Rule. From the square of the chord of half the arc subtract the square of the versed sine, and take twice the square root of the remainder.

Example. The chord of half the arc is 60, and the versed sine 36. What is the length of the chord of the arc?

Solution. $60^2 - 36^2 = 2\,304$; $\sqrt{2\,304} = 48$; and $48 \times 2 = 96$, the chord.

To compute the chord of an arc when the diameter and versed sine are given.

Multiply the versed sine by 2 and subtract the product from the diameter; then subtract the square of the remainder from the square of the diameter and take the square root of that remainder.

Example. The diameter of a circle is 100 and the versed sine of an arc 36. What is the chord of the arc?

Solution. $36 \times 2 = 72$; $100 - 72 = 28$; $100^2 - 28^2 = 9\,216$; $\sqrt{9\,216} = 96$, the chord of the arc.

To compute the chord of half an arc when the chord of the arc and the versed sine are given.

Rule. Take the square root of the sum of the squares of the versed sine and of half the chord of the arc.

Example. The chord of an arc is 96 and the versed sine 36. What is the chord of half the arc?

Solution. $\sqrt{36^2 + 48^2} = 60$.

To compute the chord of half an arc when the diameter and versed sine are given.

Rule. Multiply the diameter by the versed sine and take the square root of their product.

To compute a diameter.

Rule 1. Divide the square of the chord of half the arc by the versed sine.

Rule 2. Add the square of half the chord of the arc to the square of the versed sine and divide this sum by the versed sine.

Example. What is the radius of an arc whose chord is 96 and whose versed sine is 36?

Solution. $48^2 + 36^2 = 3\,600$; $3\,600 \div 36 = 100$, the diameter; and the radius $= 50$.

To compute the versed sine.

Rule. Divide the square of the chord of half the arc by the diameter.

To compute the versed sine when the chord of the arc and the diameter are given.

Rule. From the square of the diameter subtract the square of the chord and extract the square root of the remainder; subtract this root from the diameter and halve the remainder.

To compute the length of an arc of a circle when the number of degrees and the radius are given.

Rule 1. Multiply the number of degrees in the arc by 3.1416 multiplied by the radius and divide by 180. The result will be the length of the arc in the same unit as the radius.

Rule 2. Multiply the radius of the circle by 0.01745 and the product by the degrees in the arc.

Example. The number of degrees in an arc is 60 and the radius is 10 in. What is the length of the arc in inches?

Solution. $10 \times 3.1416 \times 60 = 1884.96$; and $1884.96 \div 180 = 10.47$ in. Or, $10 \times 0.01745 \times 60 = 10.47$ in.

To compute the length of the arc of a circle when the length is given in degrees, minutes and seconds.

Rule. (1) Multiply the number of degrees by 0.01745329 and the product by the radius. (2) Multiply the number of minutes by 0.00029 and that product by the radius. (3) Multiply the number of seconds by 0.0000048 times the radius. (4) Add together these three results for the length of the arc. (See also, table, page 57.)

Example. What is the length of an arc of 60° 10′ 5″, the radius being 4 ft?

Solution.

$$
\begin{array}{lll}
(1) & 60^\circ \times 0.01745329 \times 4 = & 4.188789 \text{ ft} \\
(2) & 10' \times 0.00029 \quad\;\; \times 4 = & 0.0116 \quad\; \text{ft} \\
(3) & 5'' \times 0.0000048 \quad \times 4 = & \underline{0.000096} \text{ ft} \\
(4) & \text{The length of the arc} = & 4.200485 \text{ ft}
\end{array}
$$

To compute the area of a sector of a circle when the degrees of the arc and the radius are given (Fig. 33).

(The degrees of the arc are the same as the angle *aob*.)

Rule. Multiply the number of degrees in the arc by the area of the whole circle and divide by 360.

Example. What is the area of a sector of a circle whose radius is 5 and length of arc 60°?

Solution. Area of circle $= 10 \times 10 \times 0.7854 = 78.54$

Hence, area of sector $= \dfrac{78.5 \times 60}{360} = 13.09$

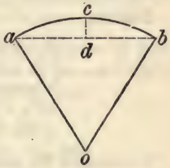

Fig. 33. Sector of Circle

Note. If the length of the arc is given in degrees and minutes, reduce it to minutes, multiply by the area of the whole circle and divide by 21 600.

To compute the area of a sector of a circle when the length of the arc and radius are given.

Rule. Multiply the length of the arc by half the length of the radius. The product is the area.

To compute the area of a segment of a circle when the chord and versed sine of the arc and the radius or diameter of the circle are given.

(The versed sine is the distance *cd*, Fig. 33.)

Rule 1. When the segment is less than a semicircle. (1) Find the area of the sector having the same arc as the segment. (2) Find the area of a triangle formed by the chord of the segment and the radii of the sector. (3) Take the difference of these areas.

Rule 2. When the segment is greater than a semicircle. Find, by the preceding rule, the area of the lesser portion of the circle and subtract it from the area of the whole circle. The remainder will be the area.

To compute the area of the surface of a sphere.

Rule. Multiply the diameter by the circumference. The product will be the area of the surface.

Example. What is the area of the surface of a sphere 10 in in diameter?

Solution. Circumference of sphere = $10 \times 3.1416 = 31.416$ in; $10 \times 31.416 = 314.16$ sq in, the area of surface of sphere.

To compute the total area of the surface of a segment of a sphere.

Rule. Multiply the height (*bc*, Fig. 34) by the circumference of the sphere and add the product to the area of the base.

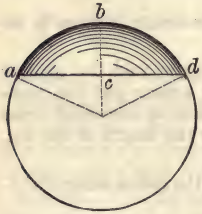

Fig. 34.
Segment of Sphere

To find the area of the base, having the diameter of the sphere and the length of the versed sine of the arc *abd*, find the length of the chord *ad* by the rule on page 58. Having, then, the length of the chord *ad* for the diameter of the base, find the area of the base.

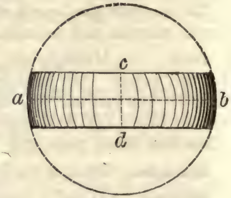

Fig. 35.
Zone of Sphere

Example. The height, *bc*, of a segment *abd*, is 36 in, and the diameter of the sphere is 100 in (Fig. 34). What is the area of the convex surface and the area of the whole surface?

Solution. $100 \times 3.1416 = 314.16$ in, the circumference of sphere
$36 \times 314.16 = 11309.76$ sq in, the area of the convex surface
$100 - (36 \times 2) = 28$
$\sqrt{100^2 - 28^2} = 96$, the chord *ad*
$96^2 \times 0.7854 = 7238.2464$ sq in, the area of the base
$11309.76 + 7238.2464 = 18548.0064$ sq in, the total area

To compute the total area of the surface of a spherical zone.

Rule. Multiply the height, *cd* (Fig. 35), by the circumference of the sphere for the convex surface and add to it the area of the two ends for the total area.

Spheroids, or Ellipsoids of Revolution

Definition. Spheroids, or ellipsoids, are figures generated by the revolution of a semiellipse about one of its diameters.

When the revolution is about the long diameter, they are PROLATE; and when it is about the short diameter, they are OBLATE.

A PROLATE SPHEROID is approximately cigar-shaped and an OBLATE SPHEROID is, in form, somewhat like a watch.

To compute the area of the surface of a spheroid.

Let $a = \frac{1}{2}$ the long axis; let $b = \frac{1}{2}$ the short axis;

let $$\frac{a^2 - b^2}{a^2} = e^2 \quad \text{or} \quad e = \sqrt{\frac{a^2 - b^2}{a^2}}$$

Then, the area of the SURFACE OF THE OBLATE SPHEROID

$$= 2\pi a^2 + \frac{\pi b^2}{e} \log\left(\frac{1+e}{1-e}\right)$$

and the area of the SURFACE OF THE PROLATE SPHEROID

$$= 2\pi b^2 + 2\pi ab \frac{\sin^{-1} e}{e}$$

In the first formula, NATURAL LOGARITHMS must be used. The natural logarithm may be obtained by multiplying the common logarithm by 2.302. The value of the expression $\sin^{-1} e$ may be determined by finding the angle whose natural sine is equal to e and dividing this angle by 57.3.

Note. Although the above formulas are complicated, no simpler rules that give correct results can be given.

Fig. 36. Circular Ring

To compute the area of the surface of a cylinder.

Rule. Multiply the length of the cylinder by the circumference of one of the ends and add to the product the areas of the two ends.

To compute the area of a circular ring (Fig. 36).

Rule. Find the area of both circles and subtract the area of the smaller from the area of the larger; the remainder will be the area of the ring.

To compute the area of the surface of a cone.

Rule. Multiply the circumference of the base by one-half the slant-height or side of the cone, for the convex area. Add to this the area of the base, for the whole area.

Example. The diameter of the base of a cone is 3 in and the slant-height 15 in. What is the area of the surface of the cone?

Solution.	3×3.1416	$= 9.4248$	= circumference of base
	$9.4248 \times 7\frac{1}{2}$	$= 70.686$ sq in	= area of convex surface
	$3 \times 3 \times 0.7854$	$= 7.068$ sq in	= area of base

Area of entire surface of cone = 77.754 sq in

To compute the area of the surface of the frustum of a cone (Fig. 37).

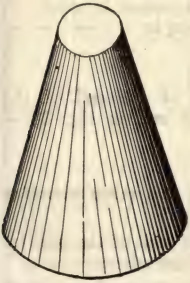

Fig. 37. Frustum of Cone

Rule. Multiply the sum of the circumferences of the two ends by the slant-height of the frustum and divide by 2, for the area of the convex surface. Add the areas of the two ends.

To compute the area of the surface of a pyramid.

Rule. Multiply the perimeter of the base by one-half the slant-height and add to the product the area of the base.

To compute the area of the surface of the frustum of a pyramid.

Rule. Multiply the sum of the perimeters of the two ends by the slant-height of the frustum, halve the product, and add to the result the areas of the two ends.

Mensuration of Solids

To compute the volume of a prism. (See page 38 for definition of a prism.)

Rule. Multiply the area of the base or end by the altitude or perpendicular height.

This rule applies to prisms with bases or ends of any shape, as long as these bases or ends are parallel.

To compute the volume of a prismoid.

Definition. A prismoid is a solid with parallel but unequal ends or bases and with quadrilateral sides.

Rule. To the sum of the areas of the two ends or bases add four times the area of the middle section parallel to them, and multiply this sum by one-sixth of the altitude or perpendicular height.

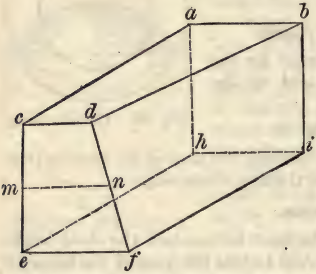

Fig. 38. Quadrangular Prismoid

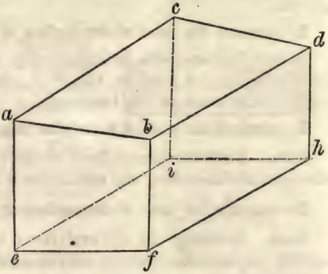

Fig. 39. Prism Truncated Obliquely

Example. What is the volume of a quadrangular prismoid, as Fig. 38, in which $ab = 6$ in, $cd = 4$ in, $ac = he = 10$ in, $ce = 8$ in, $ef = 8$ in and $ih = 6$ in?

Solution. Area of top $= \dfrac{6+4}{2} \times 10 = 50$ sq in

Area of bottom $= \dfrac{8+6}{2} \times 10 = 70$ sq in

Area of middle section $= \dfrac{6+6}{2} \times 10 = 60$ sq in

$[50 + 70 + (4 \times 60)] \times 8/6 = 480$ cu in

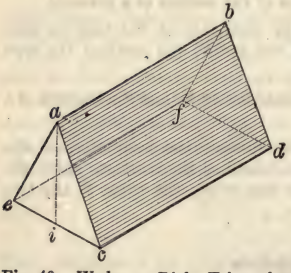

Fig. 40. Wedge or Right Triangular Prism

Note. The length of the end of the middle section (as at mn, in Fig. 38) $= \dfrac{cd + ef}{2}$

To find the volume of a prism truncated obliquely.

Rule. Multiply the area of the base by the average height of the edges.

Example. What is the volume of a truncated prism (Fig. 39) in which $ef = 6$ in, $fh = 10$ in, $ea = 10$ in, $ci = 12$ in, $dh = 10$ in and $fb = 8$ in?

Solution. Area of base $= 6 \times 10 = 60$ sq in

Average height of edges $= \dfrac{10 + 12 + 8 + 10}{4} = 10$ in

$60 \times 10 = 600$ cu in

To compute the volume of a wedge or right triangular prism when the ends are parallel and equal.

Rule. Multiply the area of one end by the length of the wedge.

To compute the volume of a wedge when the ends are not parallel.

Rule. Add together the lengths of the three edges, *ab*, *cd* and *ef* (Fig. 40); multiply their sum by the altitude or perpendicular height of the wedge, and then by the breadth of the back, and divide the product by 6.

Regular Polyhedrons

Definition. A regular polyhedron is a solid contained within a certain number of similar and equal plane faces, all of which are equal regular polygons. The following is a list of all the regular polyhedrons:

(1) The TETRAHEDRON, or pyramid.
(2) The HEXAHEDRON, or cube, which has six square faces.
(3) The OCTAHEDRON, which has eight triangular faces.
(4) The DODECAHEDRON, which has twelve pentagonal faces.
(5) The ICOSAHEDRON, which has twenty triangular faces.

To compute the volume of a regular polyhedron.

Rule 1. When the radius of the circumscribing sphere is given. Multiply the cube of the radius of the sphere by the multiplier opposite to the polyhedron in column 2 of the following table.

Rule 2. When the radius of the inscribed sphere is given. Multiply the cube of the radius of the inscribed sphere by the multiplier opposite to the polyhedron in column 3 of the table.

Rule 3. When the area of the surface of the polyhedron is given. Cube the surface given, extract the square root, and multiply the root by the multipliet opposite to the polyhedron in column 4 of the table.

Table of Factors for Determining the Volumes of Regular Polyhedrons

Figure	1 Number of sides	2 Factor for volume by radius of circumscribing sphere	3 Factor for volume by radius of inscribed circle	4 Factor for volume by surface
Tetrahedron........	4	0.5132	13.85641	0.0517
Hexahedron.........	6	1.5396	8.0000	0.06804
Octahedron.........	8	1.33333	6.9282	0.07311
Dodecahedron......	12	2.78517	5.55029	0.08169
Icosahedron.........	20	2.53615	5.05406	0.0856

To compute the volume of a cylinder.

Rule. Multiply the area of the base by the altitude or length.

To compute the volume of a cone.

Rule. Multiply the area of the base by one-third the altitude.

To compute the volume of the frustum of a cone (Fig. 41).

Rule. Add together the squares of the diameters of the two ends or bases and the product of the two diameters; multiply this sum by 0.7854, and this product by the altitude, and then divide this last product by 3.

Example. What is the volume of a frustum of a cone 9 in in height, 5 in in diameter at the base and 3 in in diameter at the top?

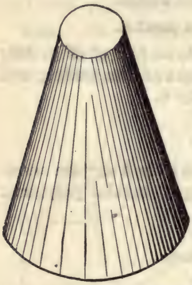

Fig. 41. Frustum of Cone

Solution. $5^2 + 3^2 = 34$. $3 \times 5 = 15$. $15 + 34 = 49$, the sum of the squares of the two diameters added to the product of the diameters of the ends. $49 \times 0.7854 = 38.4846$.

$$\frac{38.4846 \times 9}{3} = 115.4538 \text{ cu in}$$

To compute the volume of a pyramid.

Rule. Multiply the area of the base by the altitude or perpendicular height, and take one-third of the product.

To compute the volume of the frustum of a pyramid.

Rule. Find the height that the pyramid would be if the top were put on, and then compute the volume of the completed pyramid and the volume of the part added; subtract the latter from the former, and the remainder will be the volume of the frustum.

To compute the volume of a sphere.

Rule. Multiply the cube of the diameter by 0.5236.

To compute the volume of a segment of a sphere.

Rule 1. To three times the square of the radius of its base add the square of its height; multiply this sum by the height and the product by 0.5236.

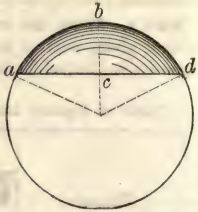

Fig. 42. Segment of Sphere

Rule 2. From three times the diameter of the sphere subtract twice the height of the segment; multiply this remainder by the square of the height and the product by 0.5236.

Example. The segment of a sphere has a radius, *ac* (Fig. 42), of 7 in for its base, and a height, *cb*, of 4 in: what is its volume?

Solution. (By Rule 1.) $3 \times 7^2 = 147$, and $147 + 4^2 = 163$, or three times the square of the radius of the base plus the square of the height. $163 \times 4 \times 0.5236 = 341.3872$ cu in = the volume of the segment.

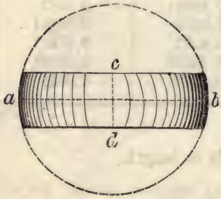

Fig. 43. Zone of Sphere

Second Solution. By the rule for finding the diameter of a circle when a chord and its versed sine are given, we find that the diameter of the sphere in this case is 16.25 in; then, by Rule 2, $(3 \times 16.25) - (2 \times 4) = 40.75$; and $40.75 \times 4^2 \times 0.5236 = 341.3872$ cu in, the volume of the segment.

To compute the volume of a spherical zone.

Definition. The part of a sphere included between two parallel planes (Fig. 43).

Rule. To the sum of the squares of the radii of the two ends add one-third of the square of the height of the zone; multiply this sum by the height and that product by 1.5708.

To compute the volume of a prolate spheroid. (See page 60.)

Rule. Multiply the square of the short axis by the long axis and this product by 0.5236.

To compute the volume of an oblate spheroid.

Rule. Multiply the square of the long axis by the short axis and this product by 0.5236.

To compute the volume of a paraboloid of revolution (Fig. 44).

Rule. Multiply the area of the base by half the altitude.

To compute the volume of a hyperboloid of revolution (Fig. 45).

Rule. To the square of the radius of the base add the square of the middle diameter; multiply this sum by the height and the product by 0.5236.

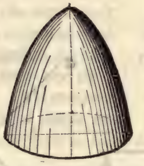

Fig. 44. Paraboloid of Revolution

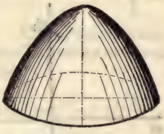

Fig. 45. Hyperboloid of Revolution

To compute the volume of any figure of revolution.

Rule. Multiply the area of the generating surface by the circumference described by its center of gravity.

To compute the volume of an excavation, where the ground is irregular and the bottom of the excavation is level (Fig. 46).

Rule. Divide the surface of the ground to be excavated unto equal squares of about 10 ft on a side, and ascertain by means of a level the height of each corner, *a*, *a*, *a*, *b*, *b*, *b*, etc., above the level to which the ground is to be excavated. Then add together the heights of all the corners that come in one square only. Next take twice the sum of the heights of all the corners that come in two squares, as *b*, *b*, *b*; next three times the sum of the heights of all the corners that come in three squares, as *c*, *c*, *c*; and then four times the sum of the heights of all the corners that belong to four squares, as *d*, *d*, *d*, etc. Add together all these quantities, and multiply their sum by one-fourth the area of one of the squares. The result will be the volume of the excavation.

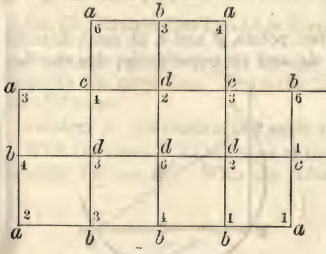

Fig. 46. Plan of Excavation

Example. Let the plan of an excavation for a cellar be as shown in Fig. 46, and the heights of each corner above the proposed bottom of the cellar be as given by the numbers in the figure. Then the volume of the cellar will be as follows, the area of each square being $10 \times 10 = 100$ sq ft:

Volume = $\frac{1}{4}$ of 100 (a's + 2 b's + 3 c's + 4 d's)

The a's in this case $= 4 + 6 + 3 + 2 + 1 + 7 + 4 = 27$

$2 \times$ the sum of the b's $= 2 \times (3 + 6 + 1 + 4 + 3 + 4) = 42$

$3 \times$ the sum of the c's $= 3 \times (1 + 3 + 4) = 24$

$4 \times$ the sum of the d's $= 4 \times (2 + 3 + 6 + 2) = 52$

145

Volume $= 25 \times 145 = 3\,625$ cu ft, the quantity of earth to be excavated.

4. GEOMETRICAL PROBLEMS

Problem 1. To bisect, or divide into equal parts, a given line, ab (Fig. 47).

From *a* and *b*, with any radius greater than half of *ab*, describe arcs intersecting in *c* and *d*. The line *cd*, connecting these intersections, will bisect *ab* and be perpendicular to it.

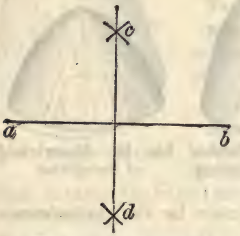

Fig. 47. Line Bisected

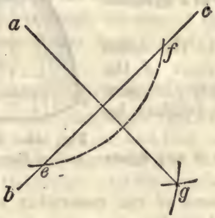

Fig. 48. Perpendicular from Point to Given Line

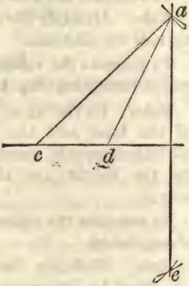

Fig. 49. Perpendicular from Point to Given Line

Problem 2. To draw a perpendicular to a given straight line from a point without it.

First Method (Fig. 48). From the point *a* describe an arc cutting the line *bc* in two places, as *e* and *f*. From *e* and *f* describe two arcs, with the same radius, intersecting in *g*; then a line drawn from *a* to *g* is perpendicular to the line *bc*.

Second Method (Fig. 49). From any two points, *d* and *c*, at some distance apart in the given line, and with radii *da* and *ca* respectively, describe arc

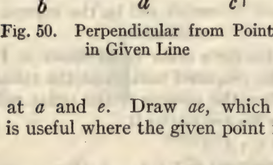

Fig. 50. Perpendicular from Point in Given Line

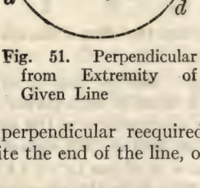

Fig. 51. Perpendicular from Extremity of Given Line

cutting at *a* and *e*. Draw *ae*, which is the perpendicular reequired. This method is useful where the given point is opposite the end of the line, or nearly so.

Problem 3. To draw a perpendicular to a straight line from a given point, a, in that line.

First Method (Fig. 50). With any radius, from the given point *a* in the line, describe arcs cutting the line in the points *b* and *c*. Then with *b* and *c* as centers, and with any radius greater than *ab* or *ac*, describe arcs cutting each other at *d*. The line *da* is the perpendicular required.

Second Method (Fig. 51), when the given point is at the end of the line. From any point, *b*, outside of the line, and with a radius *ba*, describe a semicircle passing through *a* and cutting the given line at *d*. Through *b* and *d* draw a straight line intersecting the semicircle at *e*. The line *ea* will then be perpendicular to the line *ac* at the point *a*.

Third Method (Fig. 52), or the 3, 4 and 5 Method. From the point *a* on the given line measure off 4 in, or 4 ft, or 4 of any other unit and with the same unit of measure describe an arc, with *a* as a center and 3 units as a radius. Then from *b* describe an arc with a radius of 5 units, cutting the first arc in *c*. Then *ca* is the perpendicular required. This method is particularly useful in laying out a right angle on the ground, or framing a house where the foot is used as the unit and the lines are laid off by the straight-edge.

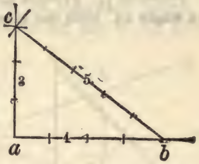

Fig. 52. Perpendicular from Extremity of Given Line

In laying out a right angle on the ground, the proportions of the triangle may be 30, 40 and 50, or any other multiple of 3, 4 and 5; and it can best be laid out with the tape. Thus, first measure off, say 40 feet from *a* (Fig. 52) on the given line; then let one person hold the end of the tape at *b*, another hold the tape at the 80-ft mark at *a*, and a third person take hold of the tape at the 50-ft mark, with his thumb and finger, and pull the tape taut. The 50-ft mark will then be at the point *c* in the line of the perpendicular.

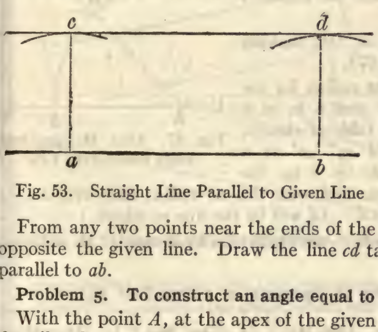

Fig. 53. Straight Line Parallel to Given Line

Problem 4. To draw a straight line parallel to a given line at a given distance away (Fig. 53).

From any two points near the ends of the given line describe two arcs about opposite the given line. Draw the line *cd* tangent to these arcs and it will be parallel to *ab*.

Problem 5. To construct an angle equal to a given angle (Fig. 54).

With the point *A*, at the apex of the given angle, as a center, and any radius, describe the arc *BC*. With the point *a*, at the vertex of the new angle, as a

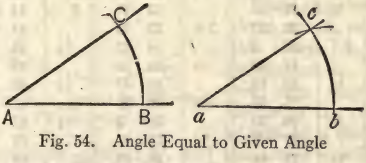

Fig. 54. Angle Equal to Given Angle

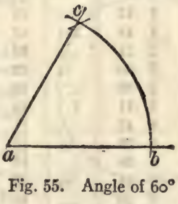

Fig. 55. Angle of 60°

center, and with the same radius as before, describe an arc, as *BC*. With *BC* as a radius and *b* as a center, describe an arc cutting the other arc at *c*. Then will *cab* be equal to the given angle *CAB*.

Problem 6. From a point on a given line to draw a line making an angle of 60° with the given line (Fig. 55).

Take any distance, as *ab*, as a radius, and with *a* as a center, describe the arc *bc*. With *b* as a center and with the same radius, describe an arc cutting the

first one at *c*. Draw from *a* a line through *c*, and it will make with *ab* an angle of 60°.

Problem 7. From a given point, A, on a given line, AE, to draw a line making an angle 45° with the given line (Fig. 56).

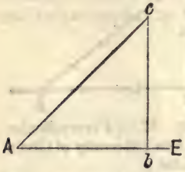

Fig. 56. Angle of 45°

Measure off from *A*, on *AE*, any distance, *Ab*, and at *b* draw a line perpendicular to *AE*. Measure off on this perpendicular *bc* equal to *Ab* and draw a line from *A* through *c*. This line *Ac* will make an angle of 45° with *AE*.

Problem 8. From any point, A, on a given line, to draw a line which will make any desired angle with the given line (Fig. 57).

To solve this problem the tables of chords on pages 81 to 89 are used. Find in the table the length of chord to a radius 1, for the given angle. Then take any radius, as large as convenient and describe an arc of a circle *bc*, with *A* as a center. Multiply the chord of the angle, found in the table, by the length of the radius *Ab*, and with the product as a new radius and with *b* as a center, describe a short arc cutting *bc* in *d*. Draw a line from *A* through *d* and it will make the required angle with *DE*.

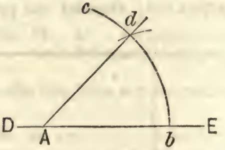

Fig. 57. Line Making Any Angle with Given Line

Example. Draw a line from *A* on *DE*, making an angle of 44° 40′ with *DE* (Fig. 57).

Solution. The largest convenient radius for the arc is 8 in. With *A* as a center and 8 in as a radius, describe the arc *bc*. In the table of chords, the chord for an angle or arc of 44° 40′ to a radius 1 is 0.76. Multiplying this by 8 in, the length of the new radius is 6.08 in; and with this as radius and with *b* as a center, describe an arc cutting *bc* in *d*. *Ad* will be the line required.

Problem 8a. To lay off a given angle approximately, by means of an ordinary two-foot rule.

* Trautwine.

Lay one leg of the rule on the paper or board with its inner edge coinciding with the given line. Open the rule until the distance between the inner edges at the ends correspond with that given for the angle in the following table; then draw a line by marking along the inner edge of the other leg, and it will give the desired angle within a very close approximation.

Problem 9. To bisect a given angle, as BAC (Fig. 58).

With *A* as a center and any radius, describe an arc, as *cb*. With *c* and *b* as centers, and any radius greater than one-half of *cb*, describe two arcs, intersecting in *d*. Draw from *A* a line through *d* and it will bisect the angle *BAC*.

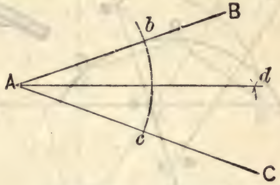

Fig. 58. Angle Bisected

Problem 10. To bisect the angle included between two lines, as AB and CD, when the vertex of the angle is not on the drawing (Fig. 59).

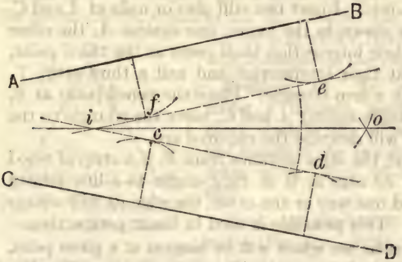

Fig. 59. Angle Bisected. Angle not on Drawing

Draw *fe* parallel to *AB* and *cd* parallel to *CD*, so that the two lines intersect, as at *i*. Bisect the angle *eid*, as in the preceding problem, and draw a line through *i* and *o* which will bisect the angle between the two given lines.

Problem 11. Through two given points, B and C, to describe an arc of a circle with a given radius (Fig. 60).

With *B* and *C* as centers and with a radius equal to the given radius, describe two arcs intersecting at *A*. With *A* as a center and the same radius, describe the arc *bc*, which will pass through the given points, *B* and *C*.

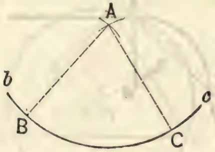

Fig. 60. Circular Arc Through Two Given Points

Problem 12. To find the center of a given circle (Fig. 61).

Draw any chord in the circle, as *ab*, and bisect this chord by the perpendicular *cd*. This line will pass through the center of the circle and *ef* will be a diameter of the circle. Bisect *ef*, and the center *o* will be the center of the circle.

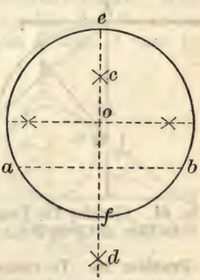

Fig. 61. Center of Given Circle

Problem 13. To draw a circular arc through three given points, as A, B and C (Fig. 62).

Draw lines from *A* to *B* and from *B* to *C*. Bisect *AB* and *BC* by the lines *aa* and *cc* and prolong these lines until they intersect at *o*, which will be the center for the arc sought. With *o* as a center and *Ao* as a radius, describe the arc *ABC*.

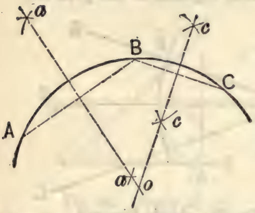

Fig. 62. Circular Arc Through Three Given Points

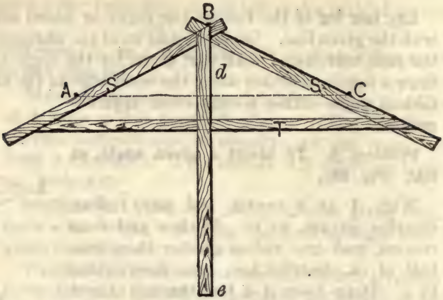

Fig. 63. Frame for Drawing Circular Arc

Problem 14. To describe a circular arc passing through three given points when the center is not available, by means of a triangle (Fig. 63).

Let *A*, *B* and *C* be the given points. Insert two stiff pins or nails at *A* and *C*. Place two strips of wood, *SS*, as shown in the figure, one against *A*, the other against *C*, and inclined so that their intersection shall come at the third point, *B*. Fasten the strips together at their intersection and nail a third strip, *T*, to their other ends, so as to make a firm triangle. Place the pencil-point at *B*, and, keeping the edges of the triangle against *A* and *C*, move the triangle to the left and right. The pencil-point will describe the required arc.

When the points *A* and *C* are at the same distance from *B*, if a strip of wood is nailed to the triangle, so that its edge *de* is at right-angles to a line joining *A* and *C*, as the triangle is moved one way or the other, the edge *de* will always point to the center of the circle. This principle is used in linear perspective.

Problem 15. To describe a circular arc which will be tangent at a given point, A, to a straight line, and pass through a given point, C, outside the line (Fig. 64).

Draw from *A* a line perpendicular to the given line. Connect *A* and *C* by a straight line and bisect this line by the perpendicular *ac*. The point where these two perpendiculars intersect is the center of the circle.

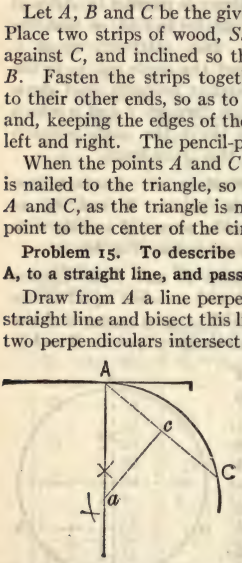

Fig. 64. Circular Arc Tangent to Line at Given Point

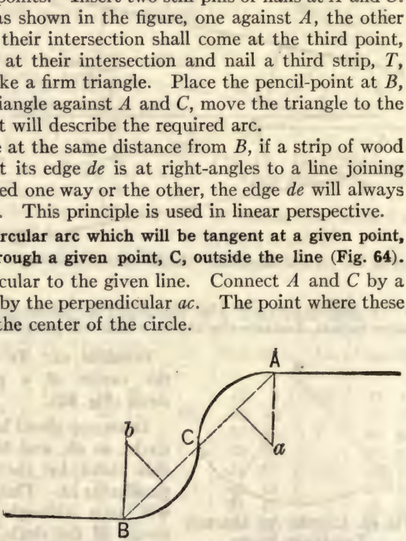

Fig. 65. Reversed Curve Between Parallel Lines

Problem 16. To connect two parallel lines by a reversed curve composed of two circular arcs of equal radius, and tangent to the lines at given points, as A and B (Fig. 65).

Join *A* and *B* and divide the line into two equal parts at *C*. Bisect *CA* and *CB* by perpendiculars. At *A* and *B* erect perpendiculars to the given lines, and the intersections *a* and *b* will be the centers of the arcs composing the required curve.

Problem 17. On a given line, as AB (Fig. 66), to construct a compound curve of three arcs of circles, the radii of the two side arcs being equal and of a given length, and their centers being in the given line. The central arc is to pass through a given point, C, on the perpendicular bisecting the given line, and is to be tangent to the other two arcs.

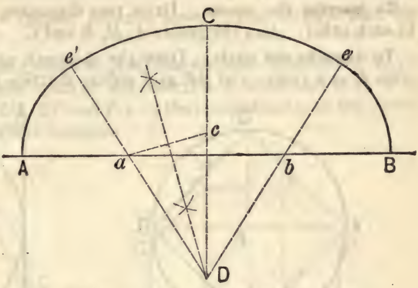

Fig. 66. Curve of Three Circular Arcs

Draw the perpendicular *CD*. Lay off *Aa*, *Bb* and *Cc*, each equal to the given radius of the side arcs; draw *ac*; bisect *ac* by a perpendicular. The intersection of this line with the perpendicular *CD* is the required center of the central arc. Through *a* and *b* draw the lines *Dc* and *De'*; from *a* and *b*, with the given radius, equal to *Aa*, *Bb*, describe the arcs *Ae'* and *Be*; from *D* as a center, and with *CD* as a radius, describe the arc *eCe'* which completes the curve required.

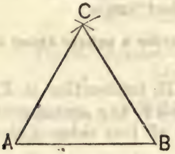

Fig. 67. Equilateral Triangle on Given Base

Problem 18. To construct a triangle upon a given straight line or base, the length of the two sides being given (Figs. 67 and 68).

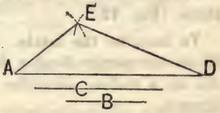

Fig. 68. Scalene Triangle on Given Base

First. An equilateral triangle (Fig. 67). With the extremities *A* and *B* of the given line as centers and with *AB* as a radius, describe arcs cutting each other at *C*. Join *AC* and *BC*.

Second. A scalene triangle (Fig. 68). Let *AD* be the given base and the other two sides be equal to *C* and *B*. With *D* as a center, and with a radius equal to *C*, describe at *E* an arc of indefinite length. With *A* as a center and with *B* as a radius, describe an arc cutting the first at *E*. Join *E* with *A* and *D*. *ADE* is the required triangle.

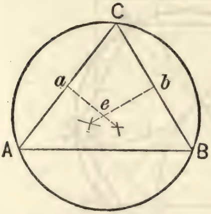

Fig. 69. Triangle and Circumscribed Circle

Problem 19. To describe a circle about a triangle (Fig. 69).

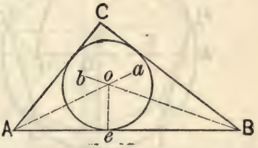

Fig. 70. Triangle and Inscribed Circle

Bisect two of the sides, as *AC* and *CB*, of the triangle, and at their centers, erect perpendicular lines, as *ae* and *be*, intersecting at *e*. With *e* as a center, and *eC* as a radius, describe a circle. It will pass through *A* and *B*.

Problem 20. To inscribe a circle in a triangle (Fig. 70).

Bisect two of the angles, *A* and *B*, of the triangle by lines cutting each other at *o*. With *o* as a center, and with *oe* as a radius, describe a circle. It will be tangent to the other two sides.

Problem 21. To inscribe a square in a circle and to describe a circle about a square (Fig. 71).

To inscribe the square. Draw two diameters, AB and CD, at right-angles to each other. Join the points A, D, B and C. $ADBC$ is the inscribed square.

To describe the circle. Draw the diagonals as before, intersecting at E, and with E as a center and AE as a radius, describe the circle.

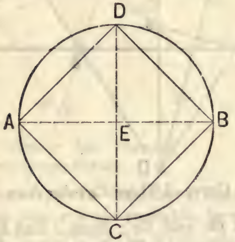

Fig. 71. Inscribed Square and Circumscribed Circle

Fig. 72. Inscribed Circle and Circumscribed Square

Problem 22. To inscribe a circle in a square and to describe a square about a circle (Fig. 72).

To inscribe the circle. Draw the diagonals AB and CD, intersecting at E. Draw the perpendicular EG to one of the sides. Then with E as a center, and EG as a radius, describe a circle. It will be tangent to all four sides of the square.

To describe the square. Draw two diameters, AB and CD, at right-angles to each other, and prolonged beyond the circumference. Draw the diameter GF, bisecting the angle CEA or BED. Draw lines through G and F perpendicular to GF, and terminating in the diagonals. Draw AD and CB to complete the square.

Problem 23. To inscribe a pentagon in a circle (Fig. 73).

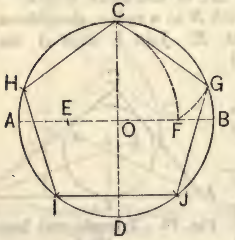

Fig. 73. Circle and Inscribed Pentagon

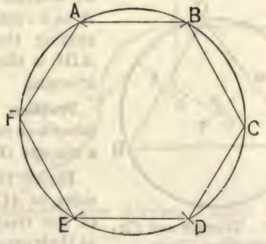

Fig. 74. Circle and Inscribed Hexagon

Draw two diameters, AB and CD, at right-angles to each other. Bisect AO at E. With E as a center and EC as a radius, cut OB at F. With C as a center and CF as a radius, cut the circle at G and H. With these points as centers and the same radius, cut the circle at I and J. Join I, J, G, C and H. $IJGCHI$ is the inscribed regular pentagon.

Problem 24. To inscribe a regular hexagon in a circle (Fig. 74).

Lay off on the circumference the radius of the circle six times, and connect the points.

Problem 25. To construct a regular hexagon upon a given straight line, AB (Fig. 75).

From A and B, with a radius equal to AB, describe arcs intersecting at O. With O as a center and a radius equal to AB, describe a circle, and from A or B lay off the lengths BC, CD, DE, EF and FA on the circumference of the circle. $ABCDEFA$ is the required regular hexagon.

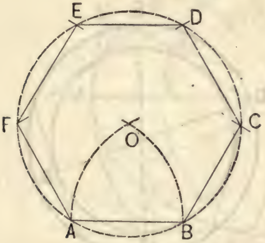

Fig. 75. Regular Hexagon on Given Line

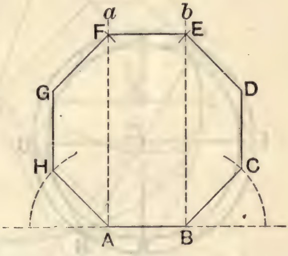

Fig. 76. Regular Octagon on Given Line

Problem 26. To construct a regular octagon upon a given straight line, AB (Fig. 76).

Produce the line AB both ways and draw the perpendiculars Aa and Bb, of indefinite length. Bisect the external angles at A and B and make the length of the bisecting lines equal to AB. From H and C draw lines parallel to Aa or Bb and equal in length to AB. From G and D as centers describe arcs, with a radius AB, cutting the perpendiculars Aa and Bb in F and E. Draw GF, FE and ED. $ABCDEFGHA$ is the required octagon.

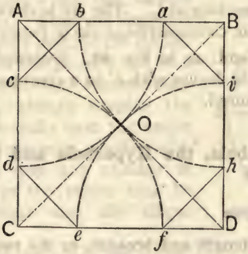

Fig. 77. Square and Inscribed Regular Octagon

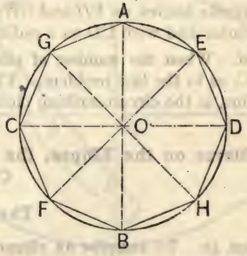

Fig. 78. Circle and Inscribed Regular Octagon

Problem 27. To construct a regular octagon in a square (Fig. 77).

Draw the diagonals AD and BC and from A, B, C and D, with a radius equal to AO, describe arcs cutting the sides of the square in *a, b, c, d, e, f, h* and *i* Draw *ai, hf. ed* and *cb*. *aihfedcba* is the required octagon.

Problem 28. To inscribe a regular octagon in a circle (Fig. 78).

Draw two diameters, *AB* and *CD*, at right-angles to each other. Bisect the angles *AOD* and *AOC* by the diameters *EF* and *GH*. *AEDHBFCGA* is the required octagon.

Problem 29. To inscribe a circle within a regular polygon.

First. When the polygon has an even number of sides, as in Fig. 79. Bisect two opposite sides at *A* and *B*, draw *AB* and bisect it at *C* by a diagonal, *DE*, connecting two opposite angles, as *D* and *E*. The circle drawn with a radius *CA* and with *C* as a center is the inscribed circle required.

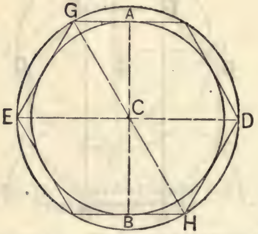

Fig. 79. Regular Polygon, Even Number of Sides, with Inscribed and Circumscribed Circles

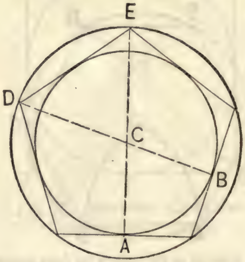

Fig. 80. Regular Polygon, Odd Number of Sides, with Inscribed and Circumscribed Circles

Second. When the number of sides is odd, as in Fig. 80. Bisect two of the adjacent sides as at *A* and *B*, and draw lines, *AE* and *BD*, to the opposite angles, and intersecting at *C*. The circle drawn with *C* as a center and *CA* as a radius is the inscribed circle required.

Problem 30. To draw a circumscribing circle around a regular polygon.

First. When the number of sides is even, as in Fig. 79. Draw two diagonals from opposite angles, as *ED* and *GH*, intersecting at *C*. The circle drawn with *C* as a center and with *CD* as a radius is the circumscribing circle required.

Second. When the number of sides is odd, as in Fig. 80. Determine the center, *C*, as in the last problem. The circle drawn with *C* as a center and *CD* as a radius, is the circumscribing circle required.

Problems on the Ellipse, the Parabola, the Hyperbola and the Cycloid

The Ellipse

Problem 31. To describe an ellipse, the length and breadth, or the two axes, being given.

First Method (Fig. 81), the two axes, AB and CD, being given. On *AB* and *CD* as diameters and from the same center, *O*, describe the circles *AGBH* and *CLDK*. Take any convenient number of points on the circumference of the outer circle, as *b*, *b'*, *b''*, etc., and from them draw lines to the center, *O*, cutting the inner circle at the points *a*, *a'*, *a''*, etc., respectively. From the points ***b***, ***b'***, etc., draw lines parallel to the shorter axis *CD*; and from the points ***a***,

a', etc., draw lines parallel to the longer axis AB, and intersecting the first set of lines at c, c', c'', etc. These last points will be points in the ellipse, and by determining a sufficient number of them, the ellipse can be drawn.

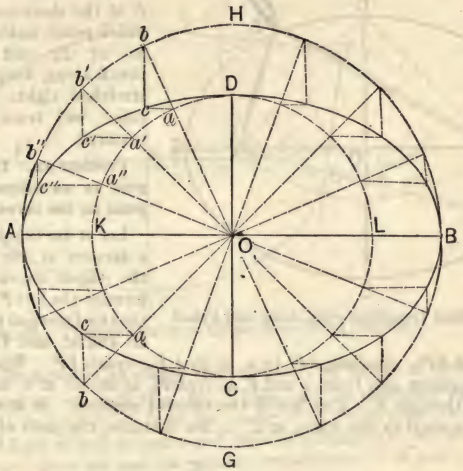

Fig. 81. Ellipse Described on Given Axes.

Second Method (Fig. 82). Take the straight-edge, made of a stiff piece of paper, cardboard or wood, and from some point as a, mark off ab equal to half the shorter diameter CD, and ac equal to half the longer diameter AB. Place the straight-edge so that the point b is on the longer and the point c on the shorter diameter. Then will the point a be over a point in the ellipse. Make on the paper a dot at a and move the straight-edge around, always keeping the points b and c over the major and minor axes respectively. In this way any number of points in the ellipse may be determined and the ellipse drawn.

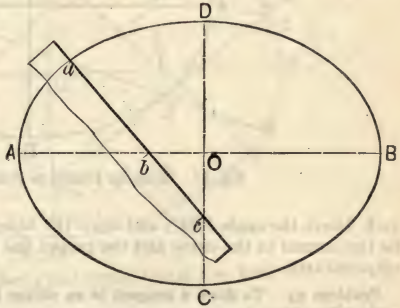

Fig. 82. Ellipse Described with Straight-Edge

Third Method (Fig. 83). Given, the two axes, AB and CD. From the point D as a center, and a radius AO, equal to one-half of AB, describe an arc cutting AB at F and F'. These two points are called the foci of the ellipse.

Note. One property of the ellipse is, that the sums of the distances of any two points on the circumference from the foci are the same. Thus $F'D + DF = F'E + EF$ or $F'G + GF$.

Fix two pins in the axis AB at F and F' and loop upon them a thread, or cord equal in length, when fastened to the pins, to AB, so as, when stretched as per dotted line FDF', it will just reach to the extremity D of the short axis. Place a pencil-point inside the chord, as at E, and move the pencil along, keeping the cord stretched tight. The pencil-point will trace the ellipse required.

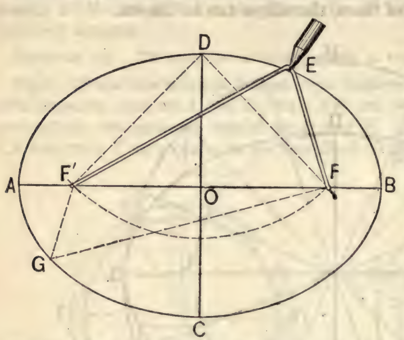

Fig. 83. Ellipse Described with String and Pencil

Problem 32. To draw a tangent to an ellipse at a given point on the curve (Fig. 84).

Let it be required to draw a tangent at the point E on the ellipse shown. First determine the foci F and F' as in the third method for describing an ellipse, and from E draw lines EF and EF'. Prolong EF' to a, so that Ea equals EF. Bisect the angle aEF by describing arcs from a and F as centers, as shown at b, and through b draw a line through E. This line is the tangent required. If it is required to draw a line normal to the curve at E, as, for instance, the joint of an elliptical

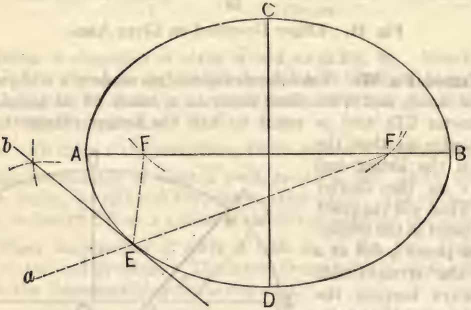

Fig. 84. Tangent Drawn to Point on Ellipse

arch, bisect the angle FEF', and draw the bisecting line through E, and it will be the normal to the curve and the proper line at that point for the joint of an elliptical arch.

Problem 33. To draw a tangent to an ellipse from a given point outside of the curve (Fig. 85).

From the given point T as a center, and with a radius equal to the distance to the nearer focus F, describe an arc of a circle. From F' as a center, and with a radius equal to the length of the longer axis of the ellipse, describe arcs cutting the circle just described at a and b. Draw lines from F' to a and b, cutting the ellipse at E and G. Draw lines from T through E and G and they will be the tangents required.

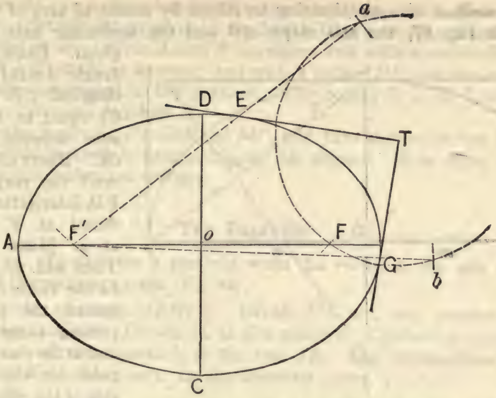

Fig. 85. Tangent Drawn to Ellipse from Point Outside

Problem 34. To describe an ellipse approximately, by means of circular arcs.

First. With arcs of two radii (Fig. 86). Take half the difference of the two axes *AB* and *CD*, and set it off from the center *O* to *a* and *c* on *OA* and *OC*; draw *ac* and on *AB* set off half *ac* from *a* to *d*; draw *di* parallel to *ac*; set off *Oe* equal to *Od*; join *ei* and draw *em* and *dm* parallel respectively to *id* and *ie*. With

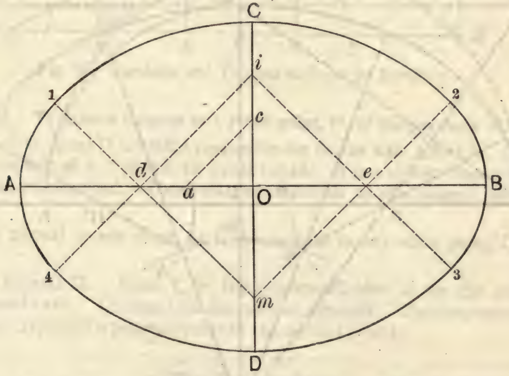

Fig. 86. Ellipse Described with Circular Arcs of Two Radii

m as a center and with a radius *mC*, describe an arc through *C*, terminating in the points 1 and 2 on *md* and *me* produced. With *i* as a center, and with *iD* as a radius, describe an arc through *D*, terminating in points 3 and 4 on *ie* and *id* produced. With *d* and *e* as centers, describe arcs through *A* and *B*, connecting the points 1 and 4 and 2 and 3. The four arcs thus described form approximately an ellipse. This method is not satisfactory when the conjugate or minor axis is less than two-thirds the transverse or major axis.

Another method of approximating an ellipse by means of arcs of two radii, is shown in Fig. 87, the axis major AB and the semiminor axis OC being given. Draw the rectangle $AabBA$, and the diagonal CB. Lay off Cc equal to the difference between OB and OC. Bisect cB at M and erect the perpendicular YD, intersecting CO produced at Y and OB, at x. Make $Ox' = Ox$. Then will x, x', and Y be the three centers required, the curves becoming tangent at D and at the corresponding point on the left-hand side of the ellipse. This method results in a curve which is slightly fuller at the haunches than the curve drawn by the preceding method.

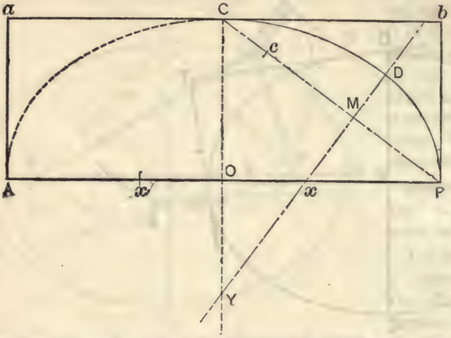

Fig. 87. Ellipse Described with Circular Arcs of Two Radii

Second. With arcs of three radii (Fig. 88). On the transverse or major axis

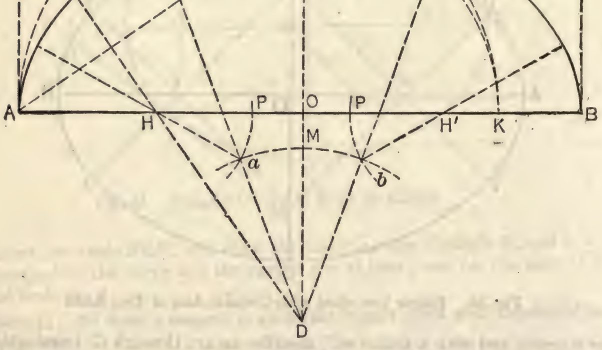

Fig. 88. Ellipse Described with Circular Arcs of Three Radii

AB draw the rectangle $AGEBA$, equal in height to OC, half the conjugate or minor axis. Draw AC and draw GD perpendicular to AC. Set off OK equal to

OC, and on AK as a diameter describe the semicircle ANK. Extend OC to L and to D. Set off OM equal to CL, and with D as a center and with a radius DM, describe an arc. With A and B as centers and with a radius OL, cut AB at P and P. From H as a center, and with a radius HP, cut the arc ab at a. H' and b are determined in like manner. The points H, a, D, b and H', are the centers of the arcs required.

Produce the lines aH, Da, Db, and bH', and thus determine the lengths of the arcs. This method is practicable for all ellipses. It is often employed for vaults, stone arches and bridges.

The Parabola

Problem 35. To describe a parabola when the vertex A, the axis AB and a point, M, of the curve are given (Fig. 89).

Construct the rectangle $ABMCA$. Divide MC into any number of equal parts, four for instance. Divide AC in like manner. Connect $A1$, $A2$ and $A3$. Through 1′, 2′, 3′, draw parallels to the axis AB. The intersections I, II and III, of these lines, are points in the required curve.

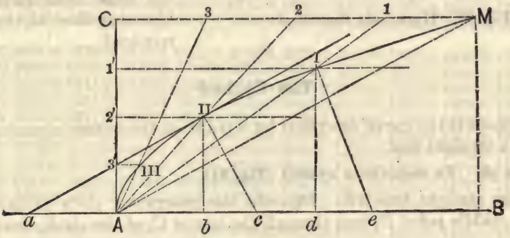

Fig. 89. Parabola and Tangent to Point on Parabola

Problem 36. To draw a tangent to a given point, II, of the parabola (Fig. 89).

From the given point II let fall a perpendicular on the axis AB at b. Produce the axis to the left of A. Make Aa equal to Ab. A line drawn through a and II is the tangent required. The lines perpendicular to the tangent are called NORMALS.

To draw a normal to any point, as I, the tangent to any other point, II being given.

Draw the normal IIc. From I, let fall a perpendicular Id, on the axis AB. Lay off de equal to bc. The line Ie is the normal required. The tangent may be drawn at I by laying off a perpendicular to the normal Ie at I.

The Hyperbola

If from any point, P, of an hyperbola, two straight lines are drawn to two fixed points, as F and F', the foci of the hyperbola, their DIFFERENCE is always the same.

Problem 37. To describe an hyperbola when a vertex, a, the given difference ab and one of the foci, F are given (Fig. 90).

Draw the axis AB of the hyperbola, with the given distance ab and the focus

F marked on it. From b lay off bF_1 equal to aF to determine the other focus F_1.

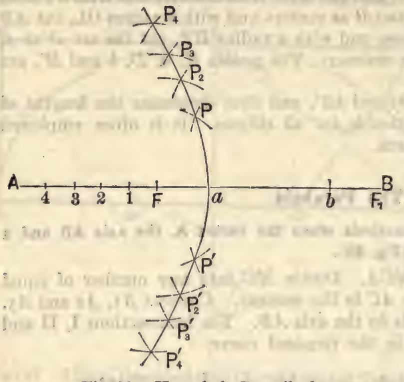

Fig. 90. Hyperbola Described

Take any point, as 1 on AB, and with $a1$ as a radius and F as a center, describe two short arcs above and below the axis. With $b1$ as a radius, and F' as a center, describe arcs cutting those just described, at P and P'. Take several points, as 2, 3 and 4, and determine the corresponding points P_2, P_3 and P_4 in the same way. The curve passing through these points is an hyperbola.

To draw a tangent to any point of an hyperbola, draw lines from the given point to each of the foci and bisect the angle thus formed. The bisecting line is the tangent required.

The Cycloid

The CYCLOID is the curve described by a point on the circumference of a circle rolling in a straight line.

Problem 38. To describe a cycloid (Fig. 91).

Draw the straight line AB. Describe the generating circle tangent to this line at its middle point D, and through the center C, of the circle, draw the line

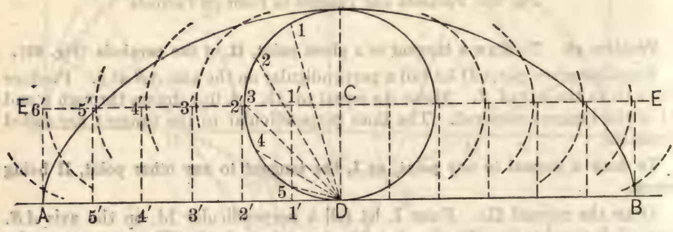

Fig. 91. Cycloid Described

EE parallel to AB. Let fall a perpendicular from C upon AB. Divide the semicircumference into any number of equal parts, for example, six. Lay off on AB and CE distances $C1'$, $1'2'$, etc., equal to the divisions of the circumference. Draw the chords $D1$, $D2$, etc. From the points $1'$, $2'$, $3'$, etc., on the line CE, with radii equal to the generating circle, describe arcs as shown. From the points $1'$, $2'$, $3'$, $4'$, $5'$, etc., on the line BA, and with radii equal respectively to the chords $D1$, $D2$, $D3$, $D4$, $D5$, describe arcs cutting the preceding arcs. The intersections are points of the required cycloid.

Table of Chords. Radius = 1.0000

Lengths and Bevels of Hip-Rafters and Jack-Rafters

Method of Determining the Lengths and Bevels. The lines *ab* and *bc* (Fig. 92) represent the outside of the walls at the angle of a building; *be* is the seat of the hip-rafter and *gf* of a jack-rafter. Draw *eh* at right-angles to *be* and make it equal to the rise of the roof; join *b* and *h* and *hb* will be the length of the hip-rafter. Through *e* draw *di* at right-angles to *bc*. With *b* as a center

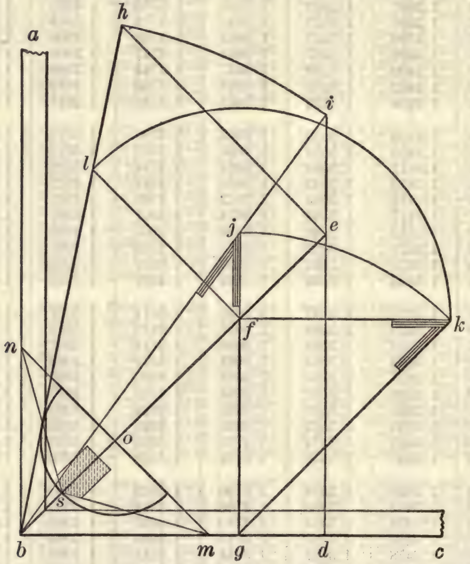

Fig. 92. Lengths and Bevels of Hip-rafters and Jack-rafters

and with the radius *bh*, describe the arc *hi*, cutting *di* in *i*. Join *b* and *i* and extend *gf* to meet *bi* in *j*; then *gj* is the length of the jack-rafter. The length of each jack-rafter is found in the same manner, by extending its seat to cut the line *bi*. From *f* draw *fk* at right-angles to *fg*; also *fl* at right-angles to *be*. Make *fk* equal to *fl* by the arc *lk*, or make *gk* equal to *gj* by the arc *jk*; then the angle at *j* is the TOP BEVEL of the jack-rafters, and the angle at *k* the DOWN BEVEL.

Backing of the Hip-Rafter. At any convenient point in *be* (Fig. 92), as *o*, draw *mn* at right-angles to *be*. From *o* describe a circle, tangent to *bh*, cutting *be* in *s*. Join *m* and *s* and *n* and *s*. The lines *ms* and *ns* form at *s* the proper angle for beveling the top of the hip-rafter.

5. TRIGONOMETRY

It is not the purpose of the author to teach the principles or uses of trigonometry; but for the benefit of those readers who have already acquired a knowledge of this science, the following convenient formulas and tables of natural sines, cosines, tangents and cotangents have been inserted. To those who know how to apply these trigonometric functions, they will often be found of great convenience and utility. These tables are taken, by permission, from Searle's Field Engineering, John Wiley & Sons, Inc., publishers.

Trigonometric Functions

Let A (Fig. 93) = angle BAC = arc BF and let the radius $AF = AB = AH = 1$
Then

$\sin A = BC$

$\cos A = AC$

$\tan A = DF$

$\cot A = HG$

$\sec A = AD$

$\operatorname{cosec} A = AG$

$\operatorname{versin} A = CF = BE$

$\operatorname{covers} A = BK = HL$

$\operatorname{exsec} A = BD$

$\operatorname{coexsec} A = BG$

$\operatorname{chord} A = BF$

$\operatorname{chord} 2A = BI = 2\,BC$

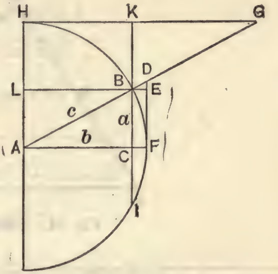

Fig. 93. Functions of Right-angled Triangle

In the right-angled triangle ABC (Fig. 93) let $AB = c$, $AC = b$ and $BC = a$
Then

(1) $\sin A = \frac{a}{c} = \cos B$

(2) $\cos A = \frac{b}{c} = \sin B$

(3) $\tan A = \frac{a}{b} = \cot B$

(4) $\cot A = \frac{b}{a} = \tan B$

(5) $\sec A = \frac{c}{b} = \operatorname{cosec} B$

(6) $\operatorname{cosec} A = \frac{c}{a} = \sec B$

(7) $\operatorname{vers} A = \frac{c-b}{c} = \operatorname{covers} B$

(8) $\operatorname{exsec} A = \frac{c-b}{b} = \operatorname{coexsec} B$

(9) $\operatorname{covers} A = \frac{c-a}{c} = \operatorname{versin} B$

(10) $\operatorname{coexsec} A = \frac{c-a}{a} = \operatorname{exsec} B$

(11) $a = c \sin A = b \tan A$

(12) $b = c \cos A = a \cot A$

(13) $c = \frac{a}{\sin A} = \frac{b}{\cos A}$

(14) $a = c \cos B = b \cot B$

(15) $b = c \sin B = a \tan B$

(16) $c = \frac{a}{\cos B} = \frac{b}{\sin B}$

(17) $a = \sqrt{(c+b)(c-b)}$

(18) $b = \sqrt{(c+a)(c-a)}$

(19) $c = \sqrt{a^2+b^2}$

(20) $C = 90° = A + B$

(21) $\text{area} = \frac{ab}{2}$

Solution of Oblique Triangles

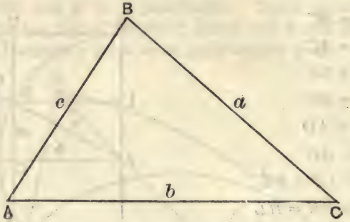

Fig. 94. Oblique-angled Triangle

	Given	Required	Formulas
(22)	A, B, a	C, b, c	$C = 180° - (A + B)$ $\quad b = \dfrac{a}{\sin A} \cdot \sin B$ $c = \dfrac{a}{\sin A} \sin (A + B)$
(23)	A, a, b	B, C, c	$\sin B = \dfrac{\sin A}{a} \cdot b$ $\quad C = 180° - (A + B)$ $c = \dfrac{a}{\sin A} \cdot \sin C$
(24)	C, a, b	$\frac{1}{2}(A + B)$	$\frac{1}{2}(A + B) = 90° - \frac{1}{2} C$
(25)	....	$\frac{1}{2}(A - B)$	$\tan \frac{1}{2}(A - B) = \dfrac{a - b}{a + b} \tan \frac{1}{2}(A + B)$
(26)	....	A, B	$A = \frac{1}{2}(A + B) + \frac{1}{2}(A - B)$ $B = \frac{1}{2}(A + B) - \frac{1}{2}(A - B)$
(27)	....	c	$c = (a + b) \dfrac{\cos \frac{1}{2}(A + B)}{\cos \frac{1}{2}(A - B)} = (a - b) \dfrac{\sin \frac{1}{2}(A + B)}{\sin \frac{1}{2}(A - B)}$
(28)	....	Area	$K = \frac{1}{2} ab \sin C$
(29)	a, b, c	A	Let $s = \frac{1}{2}(a + b + c)$; $\quad \sin \frac{1}{2} A = \sqrt{\dfrac{(s - b)(s - c)}{bc}}$
(30)	....	....	$\cos \frac{1}{2} A = \sqrt{\dfrac{s(s - a)}{bc}}$; $\quad \tan \frac{1}{2} A = \sqrt{\dfrac{(s - b)(s - c)}{s(s - a)}}$
(31)	....	....	$\sin A = \dfrac{2\sqrt{s(s - a)(s - b)(s - c)}}{bc}$ $\text{vers}\, A = \dfrac{2(s - b)(s - c)}{bc}$
(32)	....	Area	$K = \sqrt{s(s - a)(s - b)(s - c)}$
(33)	A, B, C, a	Area	$K = \dfrac{a^2 \sin B \sin C}{2 \sin A}$

Oblique Triangles. General Formulas

(34) $\sin A = \frac{1}{\operatorname{cosec} A} = \sqrt{1-\cos^2 A} = \tan A \cos A$

(35) $\sin A = 2\sin \frac{1}{2} A \cos \frac{1}{2} A = \operatorname{vers} A \cot \frac{1}{2} A$

(36) $\sin A = \sqrt{\frac{1}{2} \operatorname{vers} 2A} = \sqrt{\frac{1}{2}(1-\cos 2A)}$

(37) $\cos A = \frac{1}{\sec A} = \sqrt{1-\sin^2 A} = \cot A \sin A$

(38) $\cos A = 1 - \operatorname{vers} A = 2\cos^2 \frac{1}{2} A - 1 = 1 - 2\sin^2 \frac{1}{2} A$

(39) $\cos A = \cos^2 \frac{1}{2} A - \sin^2 \frac{1}{2} A = \sqrt{\frac{1}{2} + \frac{1}{2}\cos 2A}$

(40) $\tan A = \frac{1}{\cot A} = \frac{\sin A}{\cos A} = \sqrt{\sec^2 A - 1}$

(41) $\tan A = \sqrt{\frac{1}{\cos^2 A} - 1} = \frac{\sqrt{1-\cos^2 A}}{\cos A} = \frac{\sin 2A}{1+\cos 2A}$

(42) $\tan A = \frac{1-\cos 2A}{\sin 2A} = \frac{\operatorname{vers} 2A}{\sin 2A} = \operatorname{exsec} A \cot \frac{1}{2} A$

(43) $\cot A = \frac{1}{\tan A} = \frac{\cos A}{\sin A} = \sqrt{\operatorname{cosec}^2 A - 1}$

(44) $\cot A = \frac{\sin 2A}{1-\cos 2A} = \frac{\sin 2A}{\operatorname{vers} 2A} = \frac{1+\cos 2A}{\sin 2A}$

(45) $\cot A = \frac{\tan \frac{1}{2} A}{\operatorname{exsec} A}$

(46) $\operatorname{vers} A = 1 - \cos A = \sin A \tan \frac{1}{2} A = 2\sin^2 \frac{1}{2} A$

(47) $\operatorname{vers} A = \operatorname{exsec} A \cos A$

(48) $\operatorname{exsec} A = \sec A - 1 = \tan A \tan \frac{1}{2} A = \frac{\operatorname{vers} A}{\cos A}$

(49) $\sin \frac{1}{2} A = \sqrt{\frac{1-\cos A}{2}} = \sqrt{\frac{\operatorname{vers} A}{2}}$

(50) $\sin 2A = 2\sin A \cos A$

(51) $\cos \frac{1}{2} A = \sqrt{\frac{1+\cos A}{2}}$

(52) $\cos 2A = 2\cos^2 A - 1 = \cos^2 A - \sin^2 A = 1 - 2\sin^2 A$

(53) $\tan \frac{1}{2} A = \frac{\tan A}{1+\sec A} = \operatorname{cosec} A - \cot A = \frac{1-\cos A}{\sin A} = \sqrt{\frac{1-\cos A}{1+\cos A}}$

(54) $\tan 2A = \frac{2\tan A}{1-\tan^2 A}$

(55) $\cot \frac{1}{2} A = \frac{\sin A}{\operatorname{vers} A} = \frac{1+\cos A}{\sin A} = \frac{1}{\operatorname{cosec} A - \cot A}$

(56) $\cot 2A = \frac{\cot^2 A - 1}{2\cot A}$

Oblique Triangles. General Formulas (Continued)

(57) $\text{vers}\,\tfrac{1}{2} A = \dfrac{\tfrac{1}{2}\,\text{vers}\,A}{1 + \sqrt{1 - \tfrac{1}{2}\,\text{vers}\,A}} = \dfrac{1 - \cos A}{2 + \sqrt{2\,(1 + \cos A)}}$

(58) $\text{vers}\,2A = 2\sin^2 A$

(59) $\text{exsec}\,\tfrac{1}{2} A = \dfrac{1 - \cos A}{(1 + \cos A) + \sqrt{2\,(1 + \cos A)}}$

(60) $\text{exsec}\,2A = \dfrac{2\tan^2 A}{1 - \tan^2 A}$

(61) $\sin\,(A \pm B) = \sin A \cos B \pm \sin B \cos A$

(62) $\cos\,(A \pm B) = \cos A \cos B \mp \sin A \sin B$

(63) $\sin A + \sin B = 2 \sin \tfrac{1}{2}(A + B) \cos \tfrac{1}{2}(A - B)$

(64) $\sin A - \sin B = 2 \cos \tfrac{1}{2}(A + B) \sin \tfrac{1}{2}(A - B)$

(65) $\cos A + \cos B = 2 \cos \tfrac{1}{2}(A + B) \cos \tfrac{1}{2}(A - B)$

(66) $\cos B - \cos A = 2 \sin \tfrac{1}{2}(A + B) \sin \tfrac{1}{2}(A - B)$

(67) $\sin^2 A - \sin^2 B = \cos^2 B - \cos^2 A = \sin\,(A + B) \sin\,(A - B)$

(68) $\cos^2 A - \sin^2 B = \cos\,(A + B) \cos\,(A - B)$

(69) $\tan A + \tan B = \dfrac{\sin\,(A + B)}{\cos A \cos B}$

(70) $\tan A - \tan B = \dfrac{\sin\,(A - B)}{\cos A \cos B}$

PART II

STRENGTH OF MATERIALS AND STABILITY OF STRUCTURES

INTRODUCTION

EXPLANATION OF SUBJECT-MATTER AND NOTATION

1. Introduction to Part II

Subject-Matter of Part II. In the twenty-nine chapters of Part II are given the necessary rules, formulas and data for computing the strength and stability of all ordinary forms of building-construction, whether of wood, steel, concrete or masonry, and in fact of all but the more intricate problems of steel construction, with which few architects care to cope, and which, indeed, are more especially within the province of the engineer.

The Rules and Formulas have been reduced to their simplest forms, and, in general, require only an elementary knowledge of mathematics to understand them. The application of the formulas is explained and in most cases their derivation, and it is believed that the formulas, constants and working stresses are representative of conservative and approved contemporary practice.

Constants and Working Stresses. In the use of constants for the strength of materials, the authors and editors have been guided by the practice of leading structural engineers, by the available records of tests and by their own experience of many years as practicing and consulting architects and engineers. The varying conditions of building-construction have been taken into account and an attempt made to adapt the values to the practical conditions usually governing such construction. Every possible precaution has been taken to prevent the misapplication of rules and formulas and to insure absolute safety without undue waste of materials.

Tables. Much thought and labor have been expended on the preparation of the numerous tables, to insure their accuracy and to arrange them in the most convenient form for use by architects and builders. Many of these tables were computed by the authors and editors, all have been carefully verified, and it is believed that they may be used with perfect confidence. In all cases, unless otherwise noted, they give the same values that would be obtained by using the formulas specially referred to, while they afford a great saving of time and labor and reduce to a minimum the danger of errors in making the necessary computations.

Treatment of the Subject. Owing to the nature of the subjects treated and the large number of pages required to include them all in one book of reference, some forms of construction, such as foundations, masonry and fire-proof construction, roof-trusses, etc., are treated rather briefly. The intention is to give the data needed for immediate use rather than a complete discussion of all the principles involved. Those who wish a more complete treatise on masons' work in general are referred to the ninth edition of Kidder's Building-Construction and Superintendence, Part I, Masons' Work.* References are made in the different chapters to various other books and periodicals containing more complete information on some of the subjects.

* This has been recently completely rewritten, by Professor Thomas Nolan, and the data in it supplements the matter of Kidder's Pocket-Book.

2. Explanation of the Notation or Symbols used in Part II *

Besides the usual mathematical signs and characters in general use, the following abbreviations and symbols are frequently used:

- A area of cross-section; also, a constant used in Chapter XVI and equal to 1/18 the safe unit fiber-stress;
- $a, b, c, \ldots m$, etc., known or given distances;
- b breadth, as of beams;
- C coefficient of strength;
- c normal distance from neutral axis of cross-section of beam to most distant fiber in same;
- d diameter, as of rivets; exterior diameter; depth, as of beams;
- d_1 interior diameter;
- E modulus of elasticity;
- E_s, E_c modulus of elasticity for concrete and steel respectively (as in reinforced concrete);
- e total deformation or change in length, as in a bar;
- F shearing-modulus of elasticity;
- f maximum deflection for a beam;
- h distance between parallel axes for moments of inertia;
- I moment of inertia about a line;
- I/c section-modulus or section-factor;
- J polar moment of inertia;
- J' polar moment of inertia of bolts about shaft-axis;
- K total elastic resistance of a bar; resilience, work; also, a factor or constant used in formulas for reinforced concrete;
- l length; span of a beam;
- M bending moment;
- M_{max} maximum bending moment;
- M_1, M_2 bending moments at supports;
- M_r or SI/c moment of resistance;
- n number of loads, spans, etc.;
- P external force; concentrated load;
- P_1, P_2, P_3, etc., concentrated loads on beams;
- p pitch of rivets; eccentricity of load on column; ratio of cross-section of steel to cross-section of beam (reinforced concrete);
- r radius of curvature; radius; radius of gyration; ratio of E_s for steel to E_c for concrete (reinforced concrete);
- R_1, R_2, R_3, etc., reactions at the supports of a beam;
- S unit stress, with subscripts t, c and s for unit stress in tension, compression and shear, respectively;
- S_b buckling resistance in webs of steel beams;
- S_h horizontal unit shearing-stress in beams;
- S_e elastic limit;
- S_f modulus of rupture, or computed flexural strength;
- t_1, t_2, etc., thicknesses;
- V vertical shear;
- W weight of a bar or beam; total uniform load on beam (may include weight of beam);
- wl total uniform load on a beam (may include weight of beam);
- w weight of a cubic unit of material; uniform load on beam, per linear unit of length;

* See, also, page 3 of Part I.

x, y, z, variable distances;
α, β, etc., material constants;
ϕ constant depending upon material;
θ an angle.

Greek letters are used generally for signs of operation, for abstract numbers and for angles. Σ is employed as a symbol of summation.

The following are the Greek letters most in use:

α Alpha,	β Beta,	ϵ Epsilon,	η Eta,
θ Theta,	κ Kappa,	λ Lambda,	μ Mu,
ν Nu,	π Pi,	ρ Rho,	σ Sigma,
τ Tau,	ϕ Phi,	ψ Psi,	ω Omega.

Note. In a few places in the book it has been considered necessary or advisable by some of the associate editors to give a different meaning to one or more of the above symbols or to introduce different symbols for the meanings given in the list, but in all such cases the new symbols or meanings have been very clearly indicated.

The term BREADTH is used to denote the horizontal thickness of a beam or the smaller dimension of the cross-section of a rectangular column, post or strut, and is always measured in inches unless expressly stated otherwise.

The term DEPTH denotes the vertical height of a beam or girder, and is always measured in inches unless expressly stated otherwise.

The term LENGTH denotes the distance between supports and is always measured in feet unless expressly stated otherwise.

Abbreviations. In order to shorten the formulas, the tabulations of computations, etc., and throughout the text generally, to economize space, the units of measurement are generally abbreviated. For example, foot and feet are abbreviated, ft; inch and inches, in; pound and pounds, lb; square, sq; cubic, cu; linear, lin; inch-pound or inch-pounds, in-lb; foot-pound or foot-pounds, ft-lb; ounces, oz; horse-power, h.p.; gallons, gal; etc.; and no periods are placed after these abbreviations, except at the ends of sentences. Where the word TON is used in this volume, it always means the net ton of 2 000 lb.

CHAPTER I

EXPLANATION OF TERMS USED IN ARCHITECTURAL ENGINEERING

By

THOMAS NOLAN

PROFESSOR OF ARCHITECTURAL CONSTRUCTION, UNIVERSITY OF PENNSYLVANIA

1. Definitions of Some of the Terms Used in the Mechanics of Materials *

Terms Used in Architectural Engineering. The following terms frequently occur in discussions of the principles of architectural engineering and an understanding of their meaning is essential.

Mechanics is the branch of physics that treats of the phenomena caused by the action of forces on material bodies.

Applied Mechanics treats of the laws of mechanics as applied to construction in the useful arts, as in beams, trusses, arches, etc.

Mechanics of Materials treats of the effects of forces in causing changes in the size and shape of bodies.

Rest is the relation that exists between two points when the straight line joining them does not change in length or direction. A body is at rest relatively to a point when any point in the body is at rest relatively to the first-mentioned point.

Motion is the relation that exists between two points when the straight line joining them changes in length or direction, or in both. A body moves relatively to a point when any point in the body moves relatively to the first-mentioned point.

Force is that which changes, or tends to change, the state of rest or motion of the body acted upon. It is a cause regarding the essential nature of which we are ignorant. In the mechanics of materials we do not deal with the nature of forces, but only with the laws of their action.

Equilibrium is that condition of a body in which the forces acting upon it balance or neutralize each other; or, it is that condition of a force-system in which the resultant of the force-system is zero.

Statics is the branch of Mechanics that treats of the conditions of equilibrium. It is divided into:

(1) Statics of rigid bodies.

(2) Statics of practically incompressible fluids.

In building-construction we have to deal only with the former.

Structures are artificial constructions in which all the parts are intended to be in equilibrium and at rest relatively to each other, as in the case of a bridge-truss or roof-truss. They consist of two or more solid bodies, generally called PIECES or MEMBERS, which are connected at different parts of their surfaces called JOINTS.

* In addition to the terms defined here, many others are defined in the chapters of Part II, and especially in Chapters VI, IX, X, XIV, XV, XVI, XX and XXIV.

In general there are three conditions of equilibrium in a structure.

(1) The external forces acting upon the whole structure must balance each other. These forces are:

(*a*) The weight of the structure;

(*b*) The loads it carries;

(*c*) The upward supporting forces, reactions or resistances under or around the foundations.

(2) The forces acting upon each piece of the structure must balance each other. These forces are, for each piece:

(*a*) The weight of the piece;

(*b*) The loads it carries;

(*c*) The resistances or reactions at its joints.

(3) The forces acting upon each of the parts into which any piece may be supposed to be divided must balance each other.

The Stability of a Structure requires the fulfilment of conditions (1) and (2), that is, the ability of the structure to resist the DISPLACEMENT of any of its parts.

The Strength of a Piece or Member consists in the fulfilment of condition (3), that is, the ability of a piece to resist BREAKING.

The Stiffness of a Piece or Member consists in the ability of a piece to resist BENDING.

The Theory of Structures is divided into two parts:

(1) That which treats of strength and stiffness, dealing only with single pieces and generally known as the STRENGTH OF MATERIALS or the MECHANICS OF MATERIALS, before defined.

(2) That which treats of stability, dealing with the structures themselves.

Stress is an internal force that resists a change in shape or size caused by external forces. When the applied external forces reach certain intensities the internal stresses hold them in equilibrium.

The Intensity of a Stress is measured by the UNIT STRESS. (See Unit Stress.) The INTENSITY OF THE STRESS per square inch on any normal surface of a solid is the total stress divided by the area of the section in square inches. Thus, if a bar 10 ft long and 2 in square has a load of 8 000 lb pulling in the direction of its length, the stress on any normal section of the bar is 8 000 lb; and the intensity of the stress per square inch is 8 000 lb/4 sq in = 2 000 lb per sq in.

Deformation.* When a solid body is acted upon by an external force an alteration takes place in the volume and shape of the body, and this alteration is called the DEFORMATION. In the case of the bar given above, the deformation is the amount that the bar stretches under its load.

The Ultimate Strength is the highest unit stress a piece of material can sustain and it is the unit stress at or just before rupture.

The Working Unit Stress is the ultimate stress divided by the factor of safety.

The Safe Load is the load that a piece can support without exceeding the working unit stresses.

* In mechanics the term STRAIN is now synonymous with the term DEFORMATION. On account of the tendency to confuse the terms STRAIN and STRESS the term DEFORMATION, is used to denote change in shape and the term STRAIN is omitted in all discussions in the Pocket-Book.

The Factor of Safety * of a piece of material under stress is the ratio of the ultimate strength of the material to the actual unit stress on the section-area; or it is the number by which the ultimate unit stress must be divided to give the working unit stress. In designing a piece of material to sustain a certain load, it is required that it shall be perfectly safe under all circumstances; and hence it is necessary to make an allowance for any defects in the material, workmanship, etc. It is obvious, that, for materials of different composition, different factors of safety are required. Thus, steel being more homogeneous than wood and less liable to defects, does not require as high a factor of safety. Again, different kinds of stresses require different factors of safety. Thus, a long wooden column or strut requires a higher factor of safety than a wooden beam. As the factors of safety thus vary for different kinds of stresses and materials, the proper factors for the different kinds of stresses and conditions are given in considering the resistance of the various materials to those stresses under varying conditions.

The Unit Stress is the stress on a unit of section-area, and is usually expressed in pounds per square inch. (See Intensity of Stress.)

Dead Loads and Live Loads. The term DEAD LOAD means a load that is applied and increased gradually and that finally remains constant, such as the weight of a structure itself.

The term LIVE LOAD means a load that is applied suddenly and causes vibrations, such as a train traveling over a railway bridge. It has been found by experience that the effect of a live load on a beam or other piece of material has twice the destructive tendency of a dead load of the same magnitude or intensity. Hence a piece of material designed to carry a live load should have a factor of safety twice as large as one designed to carry a dead load. The load due to a crowd of people walking on a floor is usually considered to produce an effect which is a mean between that of a dead load and a live load, and a suitable factor of safety is adopted accordingly. In municipal ordinances and laws relating to the allowable loads for floors, the loads to be supported by the floors, exclusive of their inherent construction and stationary fixtures, are generally referred to as the LIVE LOADS no matter of what they may consist; but the term does not have the exact significance given to it by many engineers and as explained in the paragraph above.

The Modulus of Rupture or Computed Flexural Strength is the value of the UNIT FIBER-STRESS S, computed from the flexure-formula $M = SI/c$, when a beam is ruptured under a transverse load. Its value is intermediate between the ultimate tensile and compressive strengths of a material.

The Elastic Limit is that unit stress at which the deformation of a piece of material begins to increase in a faster ratio than the applied loads. It is sometimes called the ELASTIC STRENGTH.

The Modulus of Elasticity or Coefficient of Elasticity. In treatises on physics this is often called YOUNG'S MODULUS. It we take a bar of any elastic material, say one inch square, of any length, and secured at one end, and to the other apply a force, say a certain number of pounds P, pulling in the direction

* The ELASTIC LIMITS of materials must be considered in deciding upon working unit stresses and in forming a judgment of the security of materials under stress. When the elastic limit is considered the actual allowable unit stress is made a certain percentage of it, as 35 or 50%, according to varying conditions. Both ULTIMATE STRENGTHS and ELASTIC LIMITS must be taken into account in practice. But the use of the FACTOR OF SAFETY, as determined by the old method, is still a great help in the study and application of the principles of the mechanics of materials, and is used frequently in the Pocket-Book.

of its length, we shall find by careful measurement that the bar has been stretched or elongated by the action of the force. If we divide the TOTAL ELONGATION e, in inches, by the original length l of the bar, in inches, we shall have e/l, the UNIT ELONGATION ϵ, or the elongation of the bar per unit of length; and if we divide the unit stress S, developed (that is, in this case, the external force P, divided by the area of the cross-section A, or P/A) by this ratio we shall have what is known as the MODULUS OF ELASTICITY, E. Expressed in symbols and by equations, $E = S/\epsilon = \frac{P/A}{e/l}$. Hence, we may define the MODULUS OF ELASTICITY as the ratio of the unit stress to the unit deformation. Another definition is, the force which would elongate a bar of 1 sq in in cross-section to double its original length, if that could be done without exceeding the ELASTIC LIMIT of the material. This is evident from the above equation; for if $A = 1$ and $e = l$, E will equal P. These formulas apply only when the unit stress S or P/A is less than the ELASTIC LIMIT of the material. ϵ is an ABSTRACT NUMBER, because e and l are both linear quantities, and hence E is expressed in the same unit as S, that is, in POUNDS PER SQUARE INCH.

As an example of one method of determining the modulus of elasticity of any material the following illustration is given:

Suppose we have a bar of wrought iron, 2 in square and 10 ft long, securely fastened at one end, and to the other end we apply a tensile force of 40 000 lb. This force causes the bar to stretch, and by careful measurement we find the elongation to be 0.0414 in. As the bar is 10 ft, or 120 in long, if we divide 0.0414 by 120, we shall have the elongation of the bar per unit of length. Performing this operation, we have as the result, 0.00034 in. As the bar is 2 in square, the area of cross-section is 4 sq in, and hence the stress per square inch is 10 000 lb. Dividing 10 000 by 0.00034, we have, as the MODULUS OF ELASTICITY of the bar, 29 400 000 lb per sq in. This is the method generally employed to determine the MODULUS OF ELASTICITY of iron ties; but E can also be determined from the DEFLECTION of beams, and it is in that way that its values for most woods have been found. The modulus of elasticity is used in the determination of the STIFFNESS of beams.

The Moment of a Force with respect to an axis is the product obtained by multiplying the magnitude of the force by the shortest distance from the axis to its line of action. The shortest distance is called the LEVER-ARM of the force. The moment of the force is the measure of the tendency of the force to cause ROTATION about the axis. (See Chapter VI and IX.)

The Center of Gravity of a body is the point in the body through which the RESULTANT of the forces exerted by gravity upon all the particles of the body passes. A body may be balanced upon a point placed above or below the center of gravity, because the RESULTANT of any number of forces may be held in equilibrium by an equal and opposite force. Another definition of the CENTER OF GRAVITY of a body or bodies is: a point such that there is NO TENDENCY TO ROTATION about any axis drawn through it. (For center of gravity of surfaces, lines and solids, see Chapter VI.)

2. Classification of the Principal Stresses Caused in Bodies by External Forces

Tension is the stress that resists the tendency of two forces acting away from each other to PULL APART two adjoining planes of a body.

Compression is the stress that resists the tendency of two forces acting toward each other to PUSH TOGETHER two adjoining planes of a body.

Shear is the stress that resists the tendency of two equal parallel forces acting in opposite directions to cause two adjoining planes of a body to SLIDE one on the other.

Torsion is the stress that resists the tendency of forces to TWIST a body.

Combined Stresses. Parts of structures are often acted upon by several external forces which develop stresses of different character, such as combined flexure and compression, flexure and tension, flexure and torsion, shear and axial compression or tension, torsion and compression, etc.

CHAPTER II

FOUNDATIONS

By

DANIEL E. MORAN

MEMBER OF AMERICAN SOCIETY OF CIVIL ENGINEERS

1. Definition of the Word and Terms Used

Definitions. The word FOUNDATION is derived from the Latin verb FUNDARE meaning to establish or lay the base, bottom, keel or foundation of anything. The English word is used in the broadest possible way to describe the base, physical or otherwise, on which anything is supported, and in technical language it may be used to describe any part of a structure on which a subsequent operation or construction is superimposed. Thus a plaster wall may be called the FOUNDATION for a fabric to be stretched thereon and the fabric in turn becomes the FOUNDATION for various coats of paint or other decorations. More specifically and in relation to a building or other complete structure the word FOUNDATION is unfortunately applied indiscriminately (1) to construction below grade, such as footing courses, cellar walls, etc., forming the lower section of the structure; (2) to the natural material, the particular part of the earth's surface on which the construction rests; and (3) to special construction such as piling or piers used to transmit the loads of the building to firm substrata. In view of the indefinite meaning of the word it is advisable to use it either to distinguish work below grade, or below the tier of beams nearest to grade, from work above grade. In even a still more restricted sense, it might include only the work below the cellar or basement-floor to rock or other solid foundation-bed. (See Chapter II, Subdivision 29, Chapter III, Subdivision 2, and Waterproofing for Foundations, Part III.)

The Foundation-Bed. The natural material on which the construction rests is called the FOUNDATION-BED. Walls, piers and columns below grade are called, in general, FOUNDATION WALLS, PIERS AND COLUMNS to distinguish them from similar construction above grade and occasionally those only below the basement-floor are so called; the lower portions of walls, piers or columns which are spread to provide a safe base will be called FOOTING COURSES.

2. General Requirements

The Object of Foundations. The object to be borne in mind in designing any foundation is to provide a safe and permanent base for the superstructure such that the movement of the base and of the superimposed structure shall be the least possible and shall result in the least possible damage to the structure. To fully meet the above requirements the design and construction should fulfill the following conditions:

(1) **The Materials of Construction** should be proof against all deteriorating influences, or, if any of the materials are liable to deterioration they should be permanently protected.

(2) **Stresses and Future Changes.** No part of the foundation-structure should, under any combination of loadings, be stressed beyond safe limits, and the possibility of future additions or changes in the superstructure, or of a change in the use of the building, should be kept in mind.

(3) **The Load on the Natural Bed** should be kept within the safe limit for such material, under the worst conditions to which it may be exposed. In fixing this limit the amount of settlement allowable will in many cases determine the limit rather than the safe ultimate bearing capacity.

(4) **Adjoining Excavations.** The possible danger to the structure or to the stability of the foundation-bed from adjoining excavations or other disturbing causes should be guarded against as far as possible.

Physical Conditions of the Site. In order to meet the above requirements, the design should be suited to the physical conditions existing at the location. The architect or engineer should personally examine the site. He should secure all available information relative thereto and, if necessary, should make borings and tests so as to secure reliable information on which to base his design for the foundation. The first step is, therefore, a detailed and exhaustive study of the site to determine the characteristics of the foundation-bed on which the structure is to rest.

3. Geological Considerations

Character of the Foundation-Bed. A knowledge of geology is of material assistance in many cases in making a proper estimate of the character of the foundation-bed. While it is not proposed in the limits of this chapter to go into any general geological discussion the following notes may be of value in assisting the architect to determine whether any given deposits can be relied upon as affording a stable foundation-bed. Broadly speaking, as the location of the building may be in any part of the world, so the materials encountered may belong to any one of the many geological formations forming the surface of the earth. For practical purposes, however, the materials met with are roughly divided into ROCK, or materials other than rock, roughly defined as EARTH.

4. Composition and Classification of Rocks

Composition of Rocks. Rocks, and the earthy deposits derived from rocks, are composed of various minerals of which many hundred kinds are known, each varying from the others in some particular of chemical composition, form of crystallization or other characteristic. A rock or an earthy deposit may consist almost entirely of a single mineral, but it is usually composed of several distinct minerals or of mixtures of minerals. The principal classes of rock-forming minerals are:

(1) **The Silica Minerals,** composed of silica (SiO_2) in different forms;

(2) **Silicates** or combinations of silica, with various metallic bases;

(3) **Calcareous Minerals** composed of calcite or carbonate of lime ($CaCO_3$) and its combinations.

(1) Silica Minerals are different forms of the oxide of silicon, known as SILICA. In the crystalline state silica is known as

Quartz. This is the most abundant of all minerals. Owing to its hardness and insolubility it resists decomposition and abrasion better than the minerals with which it is associated and grains of it form the principal constituent of sandy deposits. In finely comminuted particles it forms a part of most of the clays.

Flint, Chert, Agate, etc., are non-crystalline varieties of silica. SILICA also forms the cementing material in many sandstones and other rocks.

(2) Silicates or combinations of silica with various bases are second in importance only to quartz.

Feldspar, an important constituent of granite and other igneous rocks, is a silicate of alumina with potash, soda or lime. When exposed to the action of water it slowly decomposes, forming silicate of alumina, the base of clay. The decomposition of granite results in the formation of clay and crystals of quartz and mica. The mica is very slowly affected and the quartz is practically unchanged.

Mica. The various mica minerals are silicates of alumina, with potash and other constituents. All varieties are soft and split into thin elastic plates. Small particles of mica are frequently found in sand.

Hornblende and Augite are silicates of lime, magnesia, iron and alumina and are of frequent occurrence.

Chlorite, Talc and Soapstone Travertine are hydrated silicates formed from other silicates by a chemical change in which a certain amount of water is absorbed. These minerals are soft and have a SOAPY FEEL. Special care should be taken in building foundations on rock of this character to guard against any sliding on the foundation-bed or between parts of the foundation-bed.

(3) **Calcareous Minerals.** The following are the principal calcareous minerals:

Calcite ($CaCO_3$), carbonate of lime, when pure and crystallized, is known as ICELAND SPAR. It is soluble in water containing CO_2. Calcite in varying degrees of purity forms limestone and marbles. As a result of its solubility caverns and voids are frequently found in limestone.

Dolomite is a carbonate of lime and magnesia. It forms the so-called DOLOMITIC LIMESTONES, which are less soluble than the calcite limestone.

Selenite, Lypsum, Alabaster, Anhydrite, Aragonite and Apatite are other and less important lime-minerals.

Classification of Rocks. Rocks are classified not only according to the minerals of which they are composed, but also according to the way in which they have been formed, as:

(1) **Igneous Rocks,** which have solidified from a molten condition;

(2) **Sedimentary Rocks,** which have been formed under water by mechanical pressure or by cementation due to chemical or organic proceesses;

(3) **Metamorphic or Plutonic Rocks,** which have changed from their original character as igneous or sedimentary rocks.

(1) **Igneous or Plutonic Rocks** are not truly stratified. They may be granular, crystalline or glassy in texture. GRANITE, SYENITE, BASALT, TRAP, etc., are examples. LAVA, PUMICE and OBSIDIAN are volcanic products, as are also certain deposits of mud and ash. With the exception of volcanic ash and mud, the igneous rocks are enduring and are not liable to present any unforeseen weakness as foundation-beds.

(2) **Sedimentary Rocks** are composed of sand, clay and other materials resulting from the breaking down of the original igneous rocks. These materials were deposited in horizontal beds generally by settling from water, and the consolidation into rock was generally affected under water by chemical, mechanical or organic action. The resultant rock-masses are stratified as a result of their constituent materials having been deposited in layers. As sand and clay are the most abundant products of rock-decomposition, so the sedimentary rocks are most frequently SILICEOUS (sandy) or ARGILLACEOUS (clayey).

Sandstone is composed of grains of sand cemented together by silica, oxides of iron, or carbonate of lime. The durability of sandstone depends on the solu-

bility of the cementing material. Carbonate of lime being soluble, sandstones containing it as cementing material yield to the weather and are not as reliable as sandstones having silica or iron oxide as cementing material.

Argillaceous Rocks contain clay with fine sand, mud, etc., and while SHALE and some other varieties are compact and hard when first uncovered, they are liable to deterioration when exposed to frost, water and other disintegrating agencies.

Limestone is composed more or less of carbonate of lime derived from the calcareous skeletons of marine animal and vegetable organisms. The character of limestone varies greatly. In so-called FOSSILIFEROUS LIMESTONES, fossils of shells or corals indicate clearly its origin, but in other limestones there are no fossils or other indications of the organic origin of the calcareous material. Admixtures of sand, clay, or other impurities may make it difficult to distinguish certain limestones from sandstones or shales.

Dolomite is a limestone containing a high percentage of magnesia.

Hydraulic Limestone is a limestone containing clay.

Chalk is a soft limestone composed of the fine shells of minute marine organisms. In general, the purer the limestone the more soluble it is and the greater the danger from fissures or caverns due to the action of water.

(3) **Metamorphic or Plutonic Rocks** are rocks which have been formed from sedimentary or igneous rocks by heat, compression, or moisture, acting alone or in combination. Thus by heat from a nearby intrusion of molten rock, limestone is changed into a crystalline marble. The general effect of METAMORPHISM is to produce a hard or durable rock.

Quartzite, a metamorphosed sandstone, is a crystalline rock of great hardness and durability.

Slate is a hard dense rock, sometimes with a well-defined tendency to split into thin plates. It has been formed by metamorphic action from clayey shales and is generally durable, but liable to slide along planes which are sometimes parallel to the cleavage, or along seams which are not parallel to the cleavage.

Gneiss is a "laminated metamorphic rock that usually corresponds mineralogically to some one of the plutonic types." * There are many varieties, best classified in accordance with the igneous rocks to which they most nearly correspond in composition. Some varieties resemble granite, but the laminated or striped aspect is generally characteristic. They are generally compact and durable.

Schists are similar to gneiss but are more finely foliated or striped. In MICA-SCHIST there are layers or foliations composed of fine grains or plates of mica. Mica-schists are liable to decomposition and it frequently happens that excavations have to be carried to great depths through decomposed rock of this character before solid rock is encountered. The material resulting from the decomposition of this rock contains fine grains of mica and other fine material and, when wet, acts as QUICKSAND.

Rock as a Foundation. All rock, if sound and not liable to slippage, is proverbially a solid foundation and capable of supporting any weight which a building is likely to impose on it. Care should be taken that rock liable to disintegration is protected from the weather, water-action, or other disintegrating influences.

5. Geology of Earthy Material

Earth and Soil. Materials other than rock, resulting from the disintegration of rock-masses, are broadly classed as EARTH. The word SOIL, when used

* Kemp.

to designate any earthy material not rock, is a misnomer, in that the idea of FERTILITY, or the lack of it, is conveyed when the word SOIL is used.

The agencies producing the disintegration of the rock masses which form or underlie the entire surface of the earth, are various, but for the purpose of this chapter they may be defined as (1) CHEMICAL and (2) MECHANICAL.

(1) **Chemical Agencies.** By CHEMICAL ACTION OF DECOMPOSITION, a rock-mass of great strength and hardness and of complicated mineralogical structure may disintegrate into a noncoherent mass of elementary minerals. Thus a feldspathic granite under the combined action of water and varying temperature disintegrates, the crystals of feldspar changing chemically and forming the hydrated silicate of aluminum known as CLAY, while the crystals of quartz, mica or hornblende, being more resistant to chemical action, retain their chemical identity but become detached particles of SAND.

(2) **Mechanical Agencies.** By the MECHANICAL AGENCIES, such as the action of frost, moving water or ice, fragments of rock are detached from the ledge of which they originally formed part and are subsequently transported, by the action of glaciers or streams, or by the wave-action in bodies of water. The attrition between the materials thus roughly thrown about breaks up the rock-masses into smaller and smaller pieces without altering the composition of the rock-material.

Flowing Water. As flowing water more readily transports small particles than large ones, the larger pieces of rock move intermittently during periods of storm or flood and are deposited as soon as the velocity of the water falls; while the smaller particles are held in suspension longer and, as the velocity of the stream falls, are deposited in the order of their size, the largest first. The rapid upper courses of streams and rivers in mountainous regions constantly roll and grind together the materials in their rocky beds, the heavy masses being moved slowly. The attrition between the fragments forms GRAVEL and SAND which are washed down stream to be deposited, as the current slackens, first as BEDS OF GRAVEL, then as SAND-BARS, and finally, in the slow-moving lower levels, as BEDS OF SILT and ALLUVIUM.

Glaciers and Glacial Deposits. The action of glaciers is similar to the action of streams. Glacial deposits, the so-called GLACIAL DRIFTS, are composed of sand, clay, gravel and boulders but, in general, there is a noticeable difference between glacial deposits and deposits made by rivers or streams. In glacial deposits the boulders frequently exhibit groovings or scratches on their faces and the edges and surfaces of the boulders are generally sharp, so that a boulder may appear as if it had been recently fractured. They rarely exhibit the smooth, water-worn and rounded surfaces found on boulders formed by water-action. Moreover, the glacial boulders may be found singly, or unassociated with other boulders in a deposit of sand or gravel. The deposit differs from a river-deposit in that there is no classification as to size; the boulders may occur on the surface or may be disseminated as if by accident through the sand and gravel forming the body of the deposit. Such glacial deposits partake of the character of a rough artificial fill without the stratification or classification as to size which is characteristic of river-deposits. In glacial moraines or dumping grounds it not infrequently happens that the surface-water finds underground passages forming so-called SINK-HOLES. A line of glacial deposits extends across the continent of North America from Long Island westward. The southern limits can be determined by reference to geological maps.

Glacial and River-Deposits Distinguished. It is important to distinguish between GLACIAL and RIVER-DEPOSITS, because, while the occurrence of glacial boulders gives, in general, little or no information as to the character and value

of the surrounding deposits, the occurrence of boulders, on the other hand, in river-deposits is generally an indication that the bed of which they form a part has been thoroughly consolidated as a result of the river-action which formed it; and, also, because such deposits generally extend down to rock or to some compact material which at the time the deposit was made was capable of resisting the action of rapidly flowing water.

Wave-Action on Lakes and Along Coast-Lines is constantly working on the materials composing the beach. Rock-masses are broken away from cliffs and ground together, producing boulders, gravel and sand. The sand, being carried more readily by the tidal currents, is deposited in the more sheltered locations and forms BEACHES, while the larger rock-masses remain near the point of origin in BARS and REEFS.

Beds of Sand, Gravel and Boulders deposited by the action of waves on the SHORES OF SEAS OR LAKES are not necessarily constant in character and tests should be made to determine the character of the material underlying such BEACH-FORMATIONS. In large river-valleys where the general formation is composed of silt or other fine material little reliance should be placed on the occurrence of BEDS OF GRAVEL, even if such beds extend over large areas. Tests should be made to determine that such beds are not underlain by less trustworthy materials. Where tributary streams discharge into large valleys they may deposit BARS OF SAND, GRAVEL and BOULDERS on top of the silt, peat, or other materials formerly deposited by the main river. (See page 136.) The general topographical conditions should serve as an indication of danger in such cases.

Results of Chemical and Mechanical Action. As a result of the foregoing brief description of the agencies at work it may be seen that ICE, WAVE and STREAM-ACTION alike tend to disrupt rock-masses and to produce boulders, gravel, sand and finer materials. The ultimate result of the combination of CHEMICAL ACTION and MECHANICAL ACTION is to reduce the hardest rocks to the finest sand, the most impalpable clays, silts and muds; and the ACTION OF WIND, WAVE and MOVING WATER is to classify such materials in deposits of grains of uniform size.

6. Materials Composing Foundation-Beds

Classification and Definitions. The following list includes the materials which are most frequently encountered, with their definitions.

Rock (solid rock, bed-rock, or ledge). Undisturbed rock-masses forming an undisturbed part of the original rock-formation.

Decayed Rock (rotten rock). Sand, clays and other materials resulting from the disintegration of rock-masses, lacking the coherent qualities but occupying the space formerly occupied by the original rock.

Loose Rock. Rock-masses detached from the ledge of which they originally formed a part.

Boulders. Detached rock-masses larger than gravel, generally rounded and worn as a result of having been transported by water or ice a considerable distance from the ledges of which they originally formed a part.

Gravel. Detached rock-particles, generally water-worn, rounded and intermediate in size between sand-particles and boulders.

Sand. Non-coherent rock-particles smaller than ¼ in in maximum dimension.

Clay. The material resulting from the decomposition and hydration of feldspathic rocks, being hydrated silicate of alumina, generally mixed with powdered feldspar, quartz and other materals.

Hard-Pan. Any strongly coherent mixture of clay or other cementing material with sand, gravel, or boulders.

Silt. A finely divided earthy material deposited from running water.

Mud. Finely divided earthy material generally containing vegetable matter and deposited from still or slowly moving water.

Dirt. Loosely used to describe any earthy material.

Soil. Earthy material capable of supporting vegetable life and generally limited to material containing decayed vegetable or animal matter.

Mould. Earthy material containing a large proportion of humus or vegetable matter.

Loam. Earthy material containing a proportion of vegetable matter.

Peat. Compressed and partially carbonized vegetable matter.

7. Characteristics of the Materials of Foundation-Beds

Solid Rock, or, as it is locally known, BED-ROCK, or LEDGE, is proverbially a solid foundation. The harder rocks, such as granite, trap, slate, sandstone, limestone, etc., are all capable of carrying the load of any ordinary structure. The softer rocks, among which may be classed the shales, shaley slates and certain marley limestones and clay stones, should not be loaded with more than 15 tons per sq ft unless they are tested for greater loads. In all cases where foundations are to be placed on what is supposed to be solid rock, care should be taken to determine whether or not the supposed solid consists of a detached portion and, also, in case the bedding-planes of the rock are inclined, if there is danger from a slip of the layer forming the foundation-bed. (See pages 139 and 146 as to side-slope locations.)

Decayed Rock. Certain igneous or metamorphic rocks such as granites, gneisses, etc., frequently disintegrate, forming so-called ROTTEN ROCK OF DECAYED ROCK. The decayed rock is generally found in conformity with the ledge of which it originally formed a part. It may retain the stratification, color and markings of the solid rock, but as a result of the disintegrating effect of water or other agents, it has lost the solid character of the original rock. When struck with a hammer it does not give the characteristic ringing sound of solid rock. It may be fairly compact and hard, or so soft as to be readily excavated with pick and shovel. The amount of such disintegrated rock overlying the solid rock varies greatly; in some cases the removal of a few inches will disclose the solid rock, in other cases the layer of decayed rock may be many feet in thickness. Test-borings in rotten rock give samples similar to the samples from solid rock; so that it frequently happens that while the foundations are planned for solid rock the excavations disclose a thick layer of rotten rock. In such cases, if it is impracticable to carry the footings down to solid rock, it may be necessary to increase the size of the footings or to adopt some other expedient.

Loose Rock. Where a rock-mass detached from the ledge of which it originally formed a part is encountered it must not be loaded in excess of the safe capacity of the material by which it is surrounded. If the voids between adjoining pieces of loose rock are completely filled in with hard-pan, compact gravel, sand, or clay, the loading may be the same as for the filling-in material, but care should be taken to determine that no voids exist. In natural rock-

fills, as in artificial rock-fills, it may happen that large voids exist between the rock-masses, forming passageways for streams of water, in which case there is extreme danger of settlements.

Boulders, Gravel and Sand. Boulders are rock-masses which have been transported by water or ice-action. Boulders are sometimes found disseminated through sand and clay and in such cases the load should be limited by the safe load of the material in which they are found. At other times boulders are found in beds, packed closely together, with the interstices filled in with gravel, sand, or clay. In such cases it is usually safe to assume that no further consolidation of the mass is likely to take place. If the bed of boulders extends to rock, they will safely sustain any load which will not crush them.

Gravel. The name GRAVEL is given to rock-particles larger than sand and smaller than the rock-masses known as BOULDERS. If compact, and if no underlying bed of poorer material exists, gravel forms a most desirable foundation-bed, equal to sand or boulders in supporting power and not as liable to be disturbed by adjoining excavations or pumping operations. If cemented it may partake of the quality of hard-pan or rock. Care, however, should be taken to determine whether or not the bed of gravel has been deposited over a layer of silt or quicksand. It is possible for this dangerous condition to exist. (See page 134.)

Sand. Sand is composed of comminuted rock-material. As quartz is the most abundant rock-mineral and as its hardness and insolubility make it highly resistant to disintegrating action, it will be found to be the principal constituent of most deposits of sand or sandy material. Grains of mica, feldspar, garnet and other minerals are frequently found. Sand is described as being FINE, MEDIUM, or COARSE, according to the size of the grains of which it is composed.

Coarse Sand may contain particles of gravel, but after eliminating all particles which will not pass a screen with 4 meshes to the inch it will be found that a large proportion of the remaining material is too coarse to pass a 40-mesh sieve.

Fine Sand, on the other hand, may contain no particles which will not pass a 20-mesh sieve, and a considerable proportion which will pass a 100-mesh sieve.

Very Fine Sand is frequently mistaken for clay and, indeed, generally does contain some clay, as clay generally contains fine sand.

Uniform Sand is sand in which there is relatively a small variation in the size of the particles.

Balanced Sand is sand in which the size of the particles varies from large to small and in which there is no great difference in the numbers of particles of each size.

Clean Sand contains no clay or loam, but a pure sand containing a large percentage of fine particles is often considered to be NOT CLEAN.

Sharp Sand is clean sand containing coarse, angular grains. When firmly grasped in the hand it gives a NOTE, due to the particles slipping over each other. Sharp sand is generally esteemed for use in mortar, although it requires more cement to fill the voids and, in the writer's opinion, is not as desirable as a clean, rounded sand.

Rounded or Buckshot Sand is composed of rounded grains not cemented together.

Quicksand. This term is popularly used to describe any fine sand, or mixture of fine sand and clay, which, when wet, forms a soft, unstable material.

In the popular mind quicksand is supposed to have some mysterious and peculiar qualities which result in a tendency to FLOW LIKE WATER and to SUCK IN animate and inanimate objects. These manifestations are connected with various theories as to the composition of quicksand, some persons insisting that quicksand must contain flakes of mica or some slippery mineral, others that the particles must be extremely fine or spherical in shape, while others contend that there must be a certain proportion of fine clay with the sand. The fact is that any uncemented sand, when subjected to the action of moving water, will move and that any sand moving as the result of the action of water becomes a quicksand. The finer the sand the more readily it is affected by a current of water, so that fine sands are more troublesome than coarse sands. A coarse sand, having large voids, permits the flow of a certain amount of water through them; if this flow has not sufficient velocity to disturb the particles of the sand, the sand can be drained without moving it. In a fine sand, having very small voids, a similar flow of water will cause the whole mass to move and there is great difficulty in draining it without producing a current sufficient to cause it to move or flow.

Excavations in Quicksand are made difficult by the tendency of the sand forming the sides of the excavation to flow into the excavation; and even if the sides of the excavation are protected, it not infrequently happens that the bottom of the excavation will LIFT, that is, there will be a movement of material from points outside of the line into the excavation, the movement in general following a curved line, and carrying the sand, under the protected side walls of the excavation. In such cases some advantage may be gained by surrounding the excavation with driven wells and draining the soil by continued pumping through sand; in other cases, wooden or steel sheeting may be driven to a point below the depth to which the excavation is to be carried, or to some underlying layer of impervious material, in which case the sheeting will act as a coffer-dam to cut off the flow of material. Such sheeting, however, must be practically watertight, as extremely fine sand, when in the condition of quicksand, will flow through very small apertures.

Quicksand as a Foundation-Bed is objectionable on account of the danger of its moving or flowing, in case it finds any outlet such as would be afforded by an adjoining excavation. Cases are known where excavations have permitted the escape of quicksand and resulted in the settlement of buildings at a very considerable distance. Such settlements have occurred not only when the footings themselves rested on quicksand, but also when they were on a stratum of coarse sand, gravel or clay of good quality which rested on an underlying stratum of quicksand.

Pockets of Quicksand. It frequently happens that pockets of fine sand are found in deposits of mixed character. Where such pockets are small in extent the fine sand may be removed and the spaces filled with concrete. Where the pockets are larger it may be necessary to carry piers through them to a better foundation-bed, to drive piles, or to resort to other expedients.

Fine Dry Sand is readily converted into quicksand by the addition of water, which fact should be carefully borne in mind in considering the load on fine sand, as a material which in dry weather is apparently safe, may be, in wet weather, an extremely dangerous one. It is frequently stated that confined quicksand is a perfectly reliable material on which to found a building. While this, as a theory, cannot be controverted, it is a dangerous assumption to act on because of the impossibility of providing that the fine sand shall be always confined.

Variation in the Size of Grains of Sand. The accompanying diagram (Fig. 1) shows graphically the results of sieve-tests on characteristic sands.

The dash-line curve (1) is an average, giving the results of sieve-tests on several so-called quicksands; the full-line curve (2) gives the result of sieve-tests on a natural sand which would be classed as a good building sand; the dot-and-dash curve (3) gives the result of sieve-tests on a fine beach sand remarkable for the

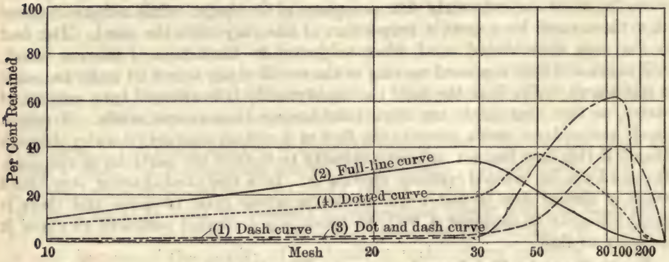

Fig. 1. Graphical Illustration of Results of Sieve-tests on Sands

uniformity of the size of its grains. For purposes of comparison and in order to show the variation in sands which appear to be substantially the same, the dotted curve (4) has been added. This shows the result of tests on a bank sand apparently as coarse as sand (2), but containing a much larger percentage of fine particles between 0.015 and 0.0055 in in diameter. Fine sand frequently contains a considerable proportion of clay. A chemical analysis of a so-called QUICKSAND from the down-town section of New York City, reported on to the writer by Dr. C. F. McKenna, is as follows:

Mark: "Commercial Cable"

Silica	73.76%
Alumina and oxide of iron	18.52%
Lime	1.60%
Magnesia	1.48%
Loss on ignition	2.26%

A rational analysis shows the following composition:

Quartz, as given	39.38%
Clay and mica, as given	23.94%
Feldspathic detritus	36.68%

On the other hand, a sample of extremely fine sand from Michigan, of which 75% passed a 200-mesh sieve, appears to be absolutely pure quartz.

Clay. When pure, clay consists of hydrated silica of alumina, the product of decomposition of feldspar. Ordinarily, various impurities are mixed with the clay, so that, in general, clay may be considered a mixture of hydrated silica of alumina with other finely divided minerals. Mixtures of clay and sand are found, varying from beds of nearly pure clay to beds of nearly pure sand, and no definite classification can be made.

The Effect of Moisture on Clay. Clay as generally found in excavations is in a plastic condition due to the presence of moisture, the amount of water present varying greatly. On drying, the clay shrinks in volume and loses its plasticity, becoming a firm and coherent mass resembling in consistency a sun-dried brick. Large masses of clay are liable to crack into a number of small

fragments during the process of drying, as the result of the shrinkage in volume. When these lumps are crushed or ground the clay becomes an extremely fine or impalpable powder. The loss in volume due to the change in the condition of the clay from a moist, plastic state to a thoroughly air-dried condition may amount to from 10% to 20% of the original volume. Compact, moist clay is impervious to water in the sense that water cannot pass through it as it would through porous sand; but when clay is exposed to water the clay gradually absorbs the water, so that eventually the entire mass becomes saturated and softened by the water.

Clay as a Foundation-Bed. Clay is not a reliable material on which to found a building; first, because of the PLASTICITY of the clay when wet, and secondly, because of its TENDENCY TO SHRINK on losing its contained moisture. The plasticity of clay increases with the percentage of contained water, so that a firm, hard clay may be converted into a liquid puddle by being agitated in the presence of a sufficient amount of water. The plasticity is also increased by pressure, as is shown by the action of clay in a brick-machine. Clay, in a foundation-bed under moderate pressure imposed on it by the footings of a structure, frequently develops this QUALITY OF PLASTICITY, the clay moving out from beneath the footing and causing serious settlements and displacements of the footings. This movement of the clay may be a local movement, as referred to each footing, in which case the clay flows from beneath the footing laterally toward the side and then upward, causing the surface of the adjacent material to rise and to form so-called BULGES OR WAVES. If this motion is uniform from the center toward the sides, the footing may settle vertically, but more frequently the movement will not be symmetrical and the footing will settle more on one side than on the other. Such movements of the clay may be reduced or prevented in some cases by the simple device of loading the surrounding soil, as, for example, by a concrete floor.

Movements of Clay Foundation-Beds. The movement of the clay may be on a larger scale, amounting to a general flow of the clay underlying the entire building toward some point where the pressure on the clay is less than the pressure resulting from the load of the building. Such general movements are more likely to happen if the building is located on the side of a hill, so that the clay finds some outlet at a point below the level of the footings. It frequently happens that adjoining excavations cause settlements to buildings at a considerable distance, by affording an outlet to a bed of clay. As noted elsewhere (pages 135 and 146), beds of clay resting on inclined strata of rock or other material are liable to move downward, sometimes with a slow, almost imperceptible movement, and at other times forming landslides of greater or less magnitude.

Protection of Clay Foundation-Beds. Where the foundation-bed is clay, or sand with a considerable amount of clay, it is advisable to protect it from water-action, so far as is possible, by a system of drains surrounding the site of the building and by diverting the surface-water from the building. Care should be taken in back-filling around exterior walls to prevent any accumulation of water which might affect the material under the footing. The neglect of such precaution has frequently resulted in serious settlements during, or immediately after, construction.

Mud, Silt, Peat and Other Unstable Materials. When the site of a structure is in a marsh or on materials which are not capable of affording a safe foundation, the only alternative is to resort to the use of wooden piles, concrete piles, or piers sunk to an underlying and firmer strata. Such special

constructions will be described under Subdivisions 27, 28 and 29, which consider wooden piles, concrete piles and piers sunk by the coffer-dam or caisson methods.

Filled Ground. All artificial fills and some natural fills are liable to a more or less uniform but continuous settlement or shrinkage due to the gradual consolidation of the material of which the fill is composed. Where the fill is of solid rock this consolidation may amount to little, but where the fill is of earth, and especially where it is of mixed materials, the shrinkage will not only be large in amount but will continue for a very long period. For example, where dirt has been thrown on top of a rock-fill each rain-storm will wash some of the dirt into the voids in the rock-fill, and this action will be continuous until all of the voids are filled in. Any vegetable matter, or other matter liable to decay and shrinkage in volume, will increase the total shrinkage of the mass. Certain natural deposits, such as beds of peat or soils containing vegetable matter, are apt to shrink in volume from the same causes. When it is necessary to found a building on such material it is inevitable that the footings will settle with the mass, notwithstanding that the unit load on the foundation-bed is so small as to be negligible. In such cases the settlements may be vertical and uniform; but if the depth of the fill under one part of the building is greater than the depth under another part, the settlements will not be uniform, as the shrinkage in the fill will, in general, be in proportion to the depth of the fill. No important building should be founded on such material and, wherever possible, the footings should be carried down through the filled-in material to some more reliable underlying stratum.

8. Allowable Loads on Materials of Foundation-Beds

General Considerations. Owing to the infinite number of variations in the materials encountered and the conditions affecting the reliability of such materials, no general or definite rule can be given, and every case should be carefully investigated before determining the allowable unit load on the foundation-bed. If the material and conditions are uniform over the entire site of the building a uniform unit load may be used, but in practice it is frequently found that entirely different conditions exist under different portions of the same building and in such cases great care must be exercised in determining the unit loads. For instance, one section of a building may rest on rock and another section on a light compressible soil or on a clay of doubtful stability. In such cases the unit load on the compressible soil or on the clay must be reduced as much as possible so as to reduce the differences in settlements between the two sections of the building to a minimum. If the entire building were on a compressible soil a very considerable settlement might be allowable, provided it was uniform; but in this particular case it is known beforehand that the part of the building on rock will not settle at all and that any settlements of other parts of the building must be considered as unequal settlements, and, as such, liable to produce cracks and distortions in the building. It is also important to remember that a certain unit load on compressible soil may be safe, in that the soil will ultimately safely support that load; but the use of that load would nevertheless be inadvisable on account of the excessive settlements. In this connection it may be said that a considerable settlement, if uniform, in a detached building may be a matter of no importance; but that where a building is to be constructed in contact with adjoining buildings or where additions are to be made to an existing building, the total amount of settlement becomes a matter of prime importance. These and other considerations, such as the character of

the proposed building and of the material composing it, should be borne in mind in selecting the unit load for any given foundation-bed, irrespective of the allowed pressure as given by building codes or by examples quoted in this chapter.

Safe Loads on Rock. The safe unit load on rock may often amount to more than the crushing strength of brickwork or stone masonry, and in nearly all cases any material worthy of the name of rock is capable of supporting from 15 to 30 tons per sq ft.

Safe Loads on Sand, Gravel and Boulders. When compact and confined laterally these materials are capable of supporting 10 tons per sq ft without appreciable settlement. It rarely happens, however, that it is advisable to load such materials with more than 5 tons per square foot.

Safe Loads on Loose Sand. By loose sand is meant sand which has not been thoroughly compacted and which may settle by its own weight independently of a superimposed load. All such materials should be tested and the unit load reduced in accordance with the result of such tests.

Loads on Fine Sand or Quicksand. It is probable that fine sand, if absolutely confined, will sustain as heavy a load as coarse sand, but in view of the fact that if afforded the slightest opportunity it is liable to lateral displacement, it is inadvisable to found any structure on such material. When it is imperative to place the footings on such material the unit load should be reduced as much as possible and preferably to less than 2 tons per sq ft, and great care should be taken to connect all footings with a continuous layer of concrete so as to prevent any flow of material into the cellar-excavation. Care should be taken, also, that any sumps, pump-pits, drainage-arrangements and sewer-connections for the building do not permit the escape of any quicksand.

Safe Loads on Hard-pan and certain cemented sands partaking of the nature of hard-pan may approximate rock in hardness and reliability. Such materials, however, are liable to soften if exposed to water. If these materials, when uncovered, are dry, experiments should be made to determine how they behave when wet, and if the level of the water in the ground is liable to change so as to reach the layer of hard-pan, the load should be correspondingly reduced. Cemented hard-pan containing gravel has been frequently loaded with more than 10 tons per sq ft. Care should be taken, however, to determine that the layer of hard-pan is continuous to a solid substratum, as it frequently happens that layers of hard-pan and fine sand or clay are deposited alternately.

Safe Loads on Clay. Ordinary clay should not be loaded with more than 2 tons per sq ft. If soft and plastic, a load of 2 tons per sq ft may produce inadmissible settlements. Clay containing so large a percentage of sand as to lose its plasticity has been loaded with from 4 to 6 tons per sq ft without undue settlements, and sand or gravel containing sufficient clay to act as a cementing material will partake of the qualities of hard-pan. In general, however, clay is the most dangerous of all the materials on which structures are founded and the unit load should be reduced to a minimum and every precaution taken to prevent the flow of material. Undue reliance should not be placed upon loading-tests of clayey soils. It is probable that a loading on a large area which will produce a movement of the clay will on a small area have no effect, so that it is unsafe to rely upon the results of a test-load applied to an area smaller than the actual supporting areas to be used. From the experience gained in the construction of large buildings in Chicago which were FLOATED on clay, the allowable unit load has been generally reduced to 2 tons per sq ft and, in the writer's experience, a load of less than 2 tons per sq ft on clay has produced settlements varying from nothing to 12 in.

9. Unit Loads on Foundation-Beds Allowed by Building Codes

Variations in Building Codes. Table I gives an outline of the requirements of different cities as to the allowable unit loads on different materials, as contained in their respective BUILDING CODES or REGULATIONS. While the allowed loads given may in some cases be based upon actual experience in the respective localities, it is more likely that they are based upon the individual experience of the authors of the codes, or are copied from other codes. The architect should, therefore, not place too much reliance on the unit loads allowed by the codes, but should investigate each case and determine for himself the proper allowance to be made.

Special Requirements of Some Building Codes. The Boston code provides that "the footing shall not overload the material on which it rests."

The New Orleans code limits the maximum load to 1 400 lb per sq ft, the entire city being on an alluvial-delta formation.

The Buffalo code limits the load on SOIL to 3½ tons per sq ft; if the SOIL is other than hard clay or gravel the supporting areas "shall be extended as directed."

The Cincinnati code limits the load on soils INFERIOR to those listed, to 1 ton per sq ft.

10. Investigation of the Site

General Considerations. To determine the character of the materials which will be encountered at the level of a foundation-bed, the architect should first get as definite information as possible from others as to their experience in making excavations and erecting buildings in that vicinity. In some localities the subsoil conditions are uniform over large areas, while in other localities important variations may occur within the limits of a city lot. Abrupt changes in surface-topography, changes in the character of the surface-soil or in the native vegetation, proximity to old or existing water-courses are suggestive of subsurface irregularities. In such cases, and in all cases where there is any doubt as to subsurface conditions, a sufficient number of exploratory borings or test-pits should be made to determine the facts. This exploratory work should go below the level of the proposed footings, should determine the ground-water level and insure that no unsuspected layer of quicksand or other unsuitable material underlies the foundation-bed. The methods in use for such explorations are as follows:

Testing in an Open Pit. For shallow work an open pit is the most satisfactory method as it allows actual inspection of the undisturbed material over a considerable area. If the excavation is in firm material, no sheet-piling or other protection may be required; but if in flowing material, or if carried deeper than adjoining footings, timber sheeting or steel sheeting should be employed. If the excavation is carried no deeper than the proposed footing-level, the underlying material should be tested by one of the methods hereinafter described.

Testing with Steel Bars. A steel bar with a pointed end or a steel pipe provided with a steel point is driven to the required depth by a maul or by a falling weight. While no samples can be obtained by this crude method, it may determine the ground-water level, and a little practice will enable one to distinguish sandy from clayey soils by the sound given out when the bar is twisted. The difficulty of driving is a rough index of the degree of the compressibility of the soil. It should be remembered, however, that any dry material will afford considerable resistance to the bar and that a small boulder will stop it; so that not much reliance can be placed on a report that the BAR DROVE HARD or that it REACHED ROCK.

Table I. Loads in Tons per Square Foot on Foundation-Beds Allowed by Building Codes

Character of foundation-bed	Richmond, Va.	Minneapolis, Minn.	Philadelphia, Pa.	Atlanta, Ga.	Portland, Ore.	Louisville, Ky.	New York City	St. Paul, Minn.	Cincinnati, O.	St. Louis, Mo.	Cleveland, O.	San Francisco, Cal.
Alluvial soils					½						½	
Firm dry loam		3		2–3		2½	3					3
Soft clay	1	1		1			1	1				1
Ordinary clay								2				
Moderately dry clay											2	
Good solid natural clay										3		
Clay in thick beds, always dry									4			
Clay in thick beds, moderately dry									2			
Dry clay								3				
Firm dry clay	3	3		2–3		2½	3					3
Hard clay	4	4	{	*8 3–4	}	4	4	4				4
Dry hard clay			3½		4						4	
Soft wet clay and sand					1½							
Dry sand mixed with clay								2				2
Ordinary clay and sand together in layers; wet and springy	2	2		2			2					
Moderately dry clay and sand					3							
Stratified clay and stone									4			
Quicksand					½						½	
Soft wet sand											1	
Wet sand								1				
Fine sand, firm and dry	3	3		2–3	4	2½	3					3
Clean dry fine sand									2			
Fine sand, compact and well cemented											4	
Dry sand								3				
Coarse compact sand									4			
Firm coarse sand								4				
Very firm coarse sand	4	4		3–4		4	4					4
Clean dry sand											2	
Stiff gravel	4			3–4		4	4					
Firm gravel		4		*8								
Cemented gravel			6									
Sand and loose gravel			3½									
Compact sand and gravel									5			
Compact sand and gravel, well cemented									8			
Firm coarse sand and gravel								6				
Gravel and coarse sand, well cemented					8						8	
Hard-pan							0–15					
Hard shale, unexposed											8	10
Rock				*15	8						8	20

* In caissons.

Testing with Post-Hole Diggers. For shallow explorations in easily excavated material, the ordinary post-hole digger used for fence-posts, or the longer and larger ones used for telegraph-poles, can be used to depths of from 6 to 8 ft.

Testing with Augers. In clay or similar material a single or double-twist carpenter's auger welded to a long rod, or the so-called POD-AUGER may give satisfactory samples. In gravel or loose and sandy material, the sides of the hole fall in, clogging the operation and destroying the samples.

Testing by Dry-Pipe Borings. A POD-AUGER or the above-described CARPENTER'S AUGER can be used inside a casing-pipe. The pipe should be driven so as to keep close to the bottom of the hole made by the auger. The pipe prevents the material falling from the sides of the hole and the auger excavates and loosens the material ahead of the pipe and facilitates driving. The above methods are not generally successful for deep holes or where gravel, boulders or compact material interferes with driving the pipe.

Testing with Wash-Pipes. For test-borings over 10 ft in depth the method in most frequent use is the WASH-PIPE METHOD. In this method a wrought-iron or steel pipe known as the CASING-PIPE or DRIVE-PIPE is driven into the earth in much the same way as in the DRY-PIPE METHOD, but the driving of the pipe is facilitated by the use of a JET OF WATER. The lower end of the casing-pipe is provided with a hollow SHOE or reinforcement, slightly larger in outside diameter than the casing. This serves to protect the pipe from injury in driving through gravel or hard-pan, and forms a hole slightly larger than the diameter of the casing. The upper end of the drive-pipe is protected from injury by an annular drive-head which has a threaded part fitting the thread on the casing-pipe and a central hole to admit the jet-pipe. The jet-pipe is small enough to permit it to freely enter the casing-pipe. The lower end is contracted so as to produce a jet-action. The upper end is connected with a water-supply which must be under considerable pressure. The driving-mechanism consists of a cast-iron weight with a central vertical hole large enough to admit the wash-pipe, and stationary verticals supporting a BLOCK-AND-FALL and an arrangement which releases the weight when it has reached a predetermined height. With this arrangement, water is continuously pumped through the jet-pipe, the length of which is regulated so that the jet-action loosens the material immediately below or AHEAD of the casing. Some of the jetting water returns to the surface outside of the casing and thus lubricates the surface in contact with the outside material. Another part of the water returns to the surface in the annular space between the wash-pipe and the casing, carrying with it particles of the material loosened by the jet. As the jet loosens and washes away the material immediately below the casing, the latter is driven deeper by repeated blows of the ram, the driving and washing being carried on at the same time. The operation is thus continuous until the top of the casing comes close to the surface of the ground, when the hammer drive-head and hose-connection are removed to permit additional lengths of pipe to be added to the casing and wash-pipes, after which the hose-connection, drive-head and hammer are replaced and the operation is resumed.

Borings can be made by this method to great depths in sand, clay or other suitable material. Samples of the material encountered are obtained by settlement from the water returning between the jet-pipe and wash-pipe. These samples are not accurate samples as the water separates the materials. The finer particles do not settle readily and the large and heavy particles may not be brought up at all. It is evident that such samples do not give any index as to the solidity of the original deposits. If large gravel, hard-pan or boulders

are encountered there will be great difficulty in forcing the casing past such obstructions. In such cases a DRILL-ROD is sometimes substituted for the JET and the obstruction broken up into small pieces or pushed to one side; but in either case it is difficult to get any sample or real indication of the character of the obstruction. If solid rock or large boulders are encountered, no further progress can be made with the casing and no sample can be obtained by this method. Resort must then be had to one of the CORE-BORING METHODS described hereafter, to determine the character of the obstruction encountered.

Testing by Core-Borings. These borings can be made through rock or boulders and accurate samples obtained. In all core-boring methods the hole is made by rotating a pipe-like tool which makes an annular cut in the rock and leaves a cylindrical core which is afterwards detached and brought to the surface by a gripping-tool called the CORE-LIFTER. The cutting is done in different ways.

Diamond Bits are annular rings fitted on the lower end of the hollow pipe used as the rotating drill-rod and furnished with a number of small diamonds arranged so as to form cutting-edges, which, when rotated in contact with the rock, gradually wear away the required annular space. The diamonds employed are known as BORT, BLACK DIAMONDS, or CARBONS, and their only resemblance to the stones used by jewelers is the necessary hardness. The carbons are skillfully secured in a soft metal bed, in sockets drilled in the bit, and they project below the bit and also sufficiently inside and outside to insure the cutting of a groove large enough to provide clearance for the bit and the attached drill-rod or pipe.

Shot-Drills. The same result is arrived at by the SHOT-DRILL METHOD, by which particles of chilled cast iron called SHOT are used as the abrasive or cutting-agent. The shot is poured loose into the hole and forced against the rock by the rotating bit.

Efficiency of Drill-Methods. Both of the drill-methods mentioned are expensive, but as they are the only methods which will give an accurate sample in rock, one or the other must be employed where the accurate determination of rock is necessary. If the core corresponds to the known underlying rock-formation and the rock is continuous for a length of from 8 to 20 ft, it is safe to assume that solid rock has been reached. If, however, the core is of different rock from the known underlying formation, the probability is that a boulder has been encountered. If the core is not continuous it may indicate that there are seams in the rock or that there are detached rock-masses. The above-described methods are used after the overlying earth has been penetrated by one of the PIPE-SINKING METHODS previously described.

The Results of Pipe-Borings are frequently misleading and misinterpreted, and great care should be taken to compare the samples with samples obtained from other borings where the exact character of the materials tested is known.

11. Loading-Tests

General Considerations. Loading-tests of the materials forming the foundation-bed are made to assist in determining its safe bearing capacity. It is not known to what extent the supporting power of a given soil varies with the area subjected to the unit load, and tests on small areas are not a safe guide for the safe load on large areas. On account of the expense involved, tests on large areas are rarely made, the usual test being on an area of about 1 sq ft. The test should be made on an undisturbed portion of the foundation-bed, leveled to receive the test-load, and for a space around the area tested, so that the

adjoining material is not reinforced or SURCHARGED by a bank of unexcavated material. The load should be applied with the least possible jar or movement of the surface in contact with the material of the foundation-bed.

Explanation of Methods. A convenient arrangement for this purpose consists of a vertical timber or post carrying a platform to receive the test-load, and having four horizontal guys at the top to keep the post in a vertical position. The bottom of the post, forming the loading-area should be approximately 12 by 12 in and its exact area should be known. The platform, sufficiently strong to support the load to be applied, should be concentric with the post and as close to the bottom of the post as practicable. The load may be pig iron, cement or sand in bags, or any other convenient material. The guys should be not less than four in number, should be attached to the top of the post and should lead horizontally so as not to pull up or down on it. Levels should be read to a point on the post above or below the load, as may be most convenient. The load should be applied gradually and with the least possible jar, care being taken, also, to keep the loading uniform on opposite sides of the post, which should be always vertical. Levels should be taken at frequent intervals during the application of the load. The level observed when the platform is first in position may be taken as zero and successive settlements referred to it. When the proposed unit load has been reached, no additional load should be added until no further settlement is observed. After this, first 50 and later 100% overload may be added and the total and periodic settlements observed. If the settlement under a test-load of twice the proposed load is not excessive, the test is considered satisfactory.

12. Topographical and Special Conditions

Excavations over Inclined Strata. In case the site of a proposed building is on a slope, and especially if the slope is steep, there may be danger from a slip of the material forming the foundation-bed. (See, also, page 135.) This may occur if there is an inclined plane of separation between layers of the underlying rock, or between the rock-surface and the material overlying the rock, or if inclined strata or beds of clay occur below the foundation-bed. Slips in such locations are the more likely to occur if water is present, as the water increases the weight of the soil and also reduces the COEFFICIENT OF FRICTION against sliding. Such conditions are frequently indicated by the appearance of springs or springy ground below the site. Where the base of the slope reaches a stream or river there may be danger from the washing away of banks which have been supporting the side slopes of the valley. In the case of deep valleys with steep clay banks, or in any location where landslides have been known to occur, great care should be taken to extend the footings to a bed that will not be affected by any landslide. It sometimes happens that there is a slow, continuous and general movement of the material forming the side slope of a valley toward the center of the valley; but such conditions are rare, fortunately, as, in general, no adequate protection is possible. In certain limestone formations there is danger from natural caves formed in the limestone by the action of water.

Excavations Near Navigable Waters. When buildings are located near navigable waters, it not infrequently happens that dredging-operations at a considerable distance induce a flow of fine sand or clay from strata underlying the adjoining banks. This has occurred where the existence of such strata was not suspected. This danger is especially to be guarded against in marshy localities adjoining waters which are, or may be, used as navigable streams, or in locations near the water-front where it is likely that docks will be constructed,

Damage from Adjoining Excavations. Common and statute laws make general provision for the protection of property-owners against damage resulting from the acts of others in making such excavations; but an owner has usually no control over such operations, whether on adjoining properties or streets, and in general will prefer the assurance of safety to the possibility of damage to his building and the expense and uncertainty of a lawsuit. While it is not always possible to guard fully against the effects of adjoining excavations, and while the expense of so doing is not always justifiable, due consideration should be given to the matter. The following suggestions, therefore, may be of value.

Depth of Adjoining Excavations. Footings adjacent to property-lines or situated where there is a probability of future additions to a building, or footings of a building which adjoins property liable to become the site of building-operations, should go down at least as deep as the maximum probable depth of the adjacent work. In estimating these probabilities, the character of the location should be taken into account. In medium-priced residential sections footings are rarely carried much deeper than 10 ft, a sufficient depth for a cellar of medium height below grade. In high-priced residential sections it is not unusual to have both a basement and a cellar, in which case a depth of cellar below grade up to 20 ft may be expected. Cellars for residences are rarely carried below 10 ft, if in reaching that depth the excavation goes below the water-level. In fact, a high water-level discourages deep excavation, not only on account of the increased difficulty and expense of excavation but also on account of the expense of waterproofing. In business sections, especially in sections of high ground-rents, there is an increasing tendency toward deep cellars, especially in boiler-rooms, where clear heights of 20 ft and over are desirable for modern water-tube boilers. The basements are frequently rentable at high figures for restaurants, vaults, stores, etc., so that in many instances the entire mechanical equipment of the building is housed below the basement in a subbasement and boiler-pit, the excavation for which extends down at least 30 ft and in special cases 60 ft below the curb; and this notwithstanding the fact that the water-level may be only from 10 to 20 ft below the curb.

Sewers and Trenches as Affecting Foundations. In cities and towns consideration should be given to the possibility of the construction of trenches in the streets. For the majority of localities it will be sufficient to consider the probable depth of a sewer of the proper depth to serve the street. In other localities it will be necessary to consider the broader question as to the probability of deeper excavations for trunk sewers, subways, etc. As such constructions are controlled by broad topographical considerations, no general rules can be given and the local city engineer should be consulted.

Foundations Near Mines, Shafts, Wells, Etc. In mining-districts local authorities should be consulted as to danger from the caving of OLD MINE-WORKINGS. No adequate provision can be made in the foundation against such widespread caving or subsidence as may result from mining-operations. In some cases, successive falls of rock-fragments from the roof may gradually fill the voids left by the mining-operations, as the loosely piled fragments of the roof will occupy more space as FILL than they did as part of the solid roof-mass. It sometimes happens that where the original working is deep, progressive falling of the roof fills all voids, and no surface-settlements result. In other cases the overburden may settle as a solid mass, causing a settlement at the surface equal to the thickness of the old working. Precautionary measures may involve the filling in of the workings, a subject outside the limits of this chapter. In the case of an important building a local mining engineer should be consulted or, if possible, the location of the building changed to a safer site. MINING-

SHAFTS, DEEP WELLS, SHAFTS FOR TUNNELS, etc., may cause disturbances of the soil, but in such cases the settlement is generally concentrated around the shaft or well, and buildings at a reasonable distance are slightly affected, if at all.

Foundations Near Tunnels and Trenches for Railroads and Subways. In large cities the necessities of transportation are increasingly calling for construction of underground RAILROADS, TUNNELS and SUBWAYS. Such constructions are generally planned to follow streets. Railroad tunnels for trunk lines can be expected to follow direct lines to centrally located stations or terminals along routes which avoid, as far as possible, difficulties of construction, condemnation of real estate and damage to high-priced properties. The depth of excavation will generally be as shallow as practicable. Where the tunnel has to dip to pass underneath some obstruction, the approach-grades will probably be at the maximum or limiting grade of the particular section.

Relation of Subways to Foundations of the Most Important Buildings. In SUBWAY-CONSTRUCTION for rapid-transit passenger service, the lines can be operated on sharper curves and with steeper grades than would be used in the case of a trunk-line railroad. This permits the lines to follow closely the lines of the city streets. For traffic-considerations the locations will, in general, follow the principal arteries of surface traffic, and stations will, in general, be located at intersections of important streets, where there is the greatest congestion of population. As such conditions are caused by the existence of trade-centers, and call for the construction of high buildings, it may readily be seen that the heaviest and most important buildings are most likely to have their foundations affected by the construction of a subway in their immediate vicinity. Where there is reason to apprehend the construction of such SUBWAYS or TUNNELS, information should be sought as to the probable depth of the excavation, the depth at which water is encountered, the character of the material, the probable width of the construction as affecting the use of sidewalk vaults, and the method to be employed in making excavations. Where the excavations for such tunnels and subways have been carried below the levels of the footings of adjoining buildings, as in Baltimore, Boston, Brooklyn, Chicago and New York City, buildings along the routes have been seriously affected. Such results have not been limited to any particular methods used in the construction of the tunnels, as even where the excavations were wholly, or partly, in rock, serious damage has been done.

13. Loads Coming on the Footings

The Loads to be Considered in the design of the footings of a structure are:

(1) **The Dead Loads,** or the loads due to the actual weight of the completed structure, ready for occupancy.

(2) **The Live Loads,** or the loads due to the occupancy of the building and also to the weight of snow on the roof.

(3) **The Wind-Loads,** or the vertical components of stresses in the structure, produced by wind-pressure.

(1) The Dead Load. The dead load of any structure can be accurately calculated. If the structure is properly designed the part of the dead load supported by each element of the foundation can be definitely stated. The total dead load becomes effective as soon as the building is completed, and remains constant thereafter unless additions or alterations are made to or in the structure.

(2) The Live Load. The live load of any structure is the sum of the roof-loads and floor-loads. In designing the roof and floors the calculations for strength are based on an assumed unit load which should be the maximum load, consistent with the probable use of the structure, to which any portion of the roof or floor may ever be subjected. The assumed live load is, therefore, probably greater than the average load for the entire area of a floor or the entire area of the roof. Moreover, as it is improbable that conditions of maximum loading will ever occur simultaneously on the roof and on all of the several floors, it is probable that the maximum load on the footings will be less than the sum of maximum loads on the roof and on the several floors.

The Minimum Live Load for an unloaded building is zero.

The Actual Live Load will vary from zero to a maximum, which maximum will generally be less than the total assumed live load.

The Ratio of the Probable Maximum Live Load to the Assumed Live Load varies in different buildings, so that no table or general rule can be given.

The Probable Maximum Live Load. As it is important to know, approximately at least, the maximum live loads to which the footings will be subjected, and as this maximum may be only a fraction of the assumed live loads, the architect should make a careful study of the conditions of loading to which the building will probably be subjected and estimate the probable maximum live load for the entire building.

Data for Estimating Live Loads. (See, also, Chapter XXI, pages 718 to 721.) In estimating the probable maximum live loads for different uses, the following notes may be of value. In certain buildings the assumed unit loading on the roof and on parts of each floor may be reached at various times, but it is unlikely that the maximum loading of all parts of the building will occur at the same time. In buildings of many stories the probability of having maximum loads on all of the floors at the same time decreases with the number of stories.

Ordinary Household and Office-Furniture weighs from 5 to 10 lb per sq ft of space occupied. While safes, bookcases or filing-cases may produce local loadings of from 10 to 100 lb per sq ft, the average load on office-floors rarely reaches 10 lb per sq ft.

Residences, Apartments and Parts of Hotels not used for public assemblies are rarely loaded with more than 5 lb per sq ft of floor-area.

Retail and Wholesale Stores require a large percentage of the floor-area for the use of salespeople and customers, and not over 50% of the floor-area is used for the storage of stock. In estimating the weight of miscellaneous stocks, an average between the lightest and heaviest classes should be taken for the weight per cubic foot, and also, in figuring the total space occupied by stock, an average should be taken between the maximum and minimum amount of stock carried. In RETAIL DRY-GOODS STORES the floor-load for the entire building may amount to not more than 25 lb per sq ft, but in WHOLESALE STORES, and especially in grocery and hardware stores, the average load may greatly exceed this figure.

In Workshops, Loft-Buildings and Buildings for Manufacturing, the actual live loads will, of course, vary with the class of material handled and the weight of the machinery used, and no general estimate can be made. Where the character of the occupancy to be expected is known it is possible to make a close approximation of the weights of machinery, fixtures and average stock on each floor.

Storehouses. In buildings used, in whole or in part, for STORAGE PURPOSES a floor may be used for light, bulky materials which, when stowed so as to leave

gangways and working-spaces, will give a resultant load much below the assumed load. On the other hand, the heaviest materials may be compactly piled from floor to ceiling in defiance of building regulations, posted notices and common sense. Raw materials or crated or baled materials can be packed closer than miscellaneous articles, and are therefore liable to increase the loads.

The Ratio of the Total Probable Maximum Live Load to the Total Assumed Live Load having been determined for the entire building, the probable maximum live load for any element of the footing may be readily obtained by multiplying the assumed or calculated live load for that element by this ratio.

(3) **The Wind-Load** is generally calculated on the assumption that the wind may exert a uniform pressure, frequently taken at 30 lb per sq ft, on the entire external area of any side of the building. This assumption makes no deduction for the protecting influences of adjoining buildings. In a building of any size it is improbable that the maximum pressure will be reached over the entire exposed area at the same instant of time, and consequently, if the assumed pressure represents the maximum pressure, the average, at any time, will be less than the calculated total.

General Effect of Wind-Pressure. The horizontal pressure of the wind tends to increase the load on footings on the leaward side of the building and to decrease the load on footings on the windward side. In many buildings diagonal bracing, called wind-bracing, or other special construction, is used to prevent the building from being deformed by the wind-pressure and to convert the horizontal stresses due to the wind-pressure into vertical components, acting along defined lines of support, that is, into either uplifts or loads on certain walls, piers or columns. Where the uplift on any element of the structure is less than the dead load on the same element, the uplift is ignored. Where the vertical component increases the compression in any element it is called the WIND-LOAD IN THAT ELEMENT of construction and on the corresponding footing. The design is generally based upon concentrating all of the wind-load on certain external footings. If, on account of the general rigidity of the building, or on account of any other reason, the wind-stresses reach footings not designed to receive wind-loads, the amounts figured on the external footings will be reduced correspondingly. It is probable that the maximum effect of the wind results from a series of impulses of short duration and that the effect of such pulsations may be partially overcome by the inertia and elasticity of the buildings; so that the resultant load reaching the footing may be only a part of the theoretical load for the instant during which the maximum pressure is exerted. (See, also, Chapter XXIX, Wind-Bracing of Tall Buildings.)

The Probable Maximum Wind-Load acting on the footing is, therefore, less than the theoretical load due to the maximum wind-pressure. If the assumed wind-load represents approximately the maximum wind-pressure, as recorded by a wind-gauge, it would appear safe to assume that only 50% of the assumed wind-load would act to produce a settlement in the footings of a building. Some authors recommend that in proportioning footings all wind-loads be ignored; but this, especially in the case of high and narrow buildings, is manifestly improper. The minimum wind-load is negative, being actually an uplift from which the load may vary to the maximum, but the maximum will be reached only at rare intervals and will endure for a short period only.

The Combined Wind-Load and Live Load. It is improbable that the maximum wind-load and the maximum live load will occur at the same time, which consideration should be borne in mind when the estimate is being made as to the effective wind-load.

14. Assumed Loads Specified by Building Codes

Table II. Requirements of Building Codes for Assumed Loads for Office-Buildings

City	Requirements
Atlanta, Ga.	Live load, 75 lb per sq ft above 1st floor; 150 lb per sq ft on 1st floor Footings designed for dead load and 60% of live load and wind-load
Boston, Mass.	Live load, 100 lb per sq ft. Wind-load, 30 lb per sq ft where erected in open spaces; in built-up districts, 25 lb at the 10th story, 2½ lb more for each succeeding upper story, up to a maximum of 35 lb to the 14th story and above
Buffalo, N. Y.	Live load, 70 lb per sq ft. Wind-load, 30 lb per sq ft. Foundations designed for the acting average loads in the completed and occupied building and not the theoretical or occasional loads
Minneapolis, Minn.	Live load, 75 lb per sq ft above the first floor; 100 lb for first floor. Wind-load, 30 lb per sq ft. Roof and top floor, full live load. For each succeeding lower floor, a reduction of 5% until 50% is reached, such reduction being used for the remaining floors
Richmond, Va.	Foundations designed for 60% of the live load
St. Louis, Mo.	Live load, 70 lb per sq ft; first floor, 150 lb. Loads carried by the soil, total dead load and 10 lb per sq ft of all the floor-area. Wind-load, 30 lb per sq ft
St. Paul, Minn.	Live load, 60 lb per sq ft above the first floor. First floor, 125 lb. Wind-load, 30 lb. Roof and top floor, full load; for each lower floor, a reduction of 5% until 50% of the full live load is reached, when such reduced load shall be used for the remaining floors. Footings designed for dead load and live load
Cincinnati, O.	Live load, 50 lb per sq ft above first floor; 100 lb for first floor. Live load reduced by 5% for each floor below the top until 20% is reached, when such reduced loads shall be used for remaining floors. Wind-load, 20 lb per sq ft above surrounding buildings
Chicago, Ill.	Live load, 50 lb per sq ft. 50% of the live load used for piles. Piers designed for 85% of live load on top floor and reduced by 5% for each lower floor until 50% is reached, when such reduced loads shall be used for the remaining floors. Wind-load 20 lb per sq ft
New York City.	Footings designed for 60% of the live load
Cleveland, O.	Live load 60 lb per sq ft in offices proper. 100 lb per sq ft in halls, lobbies, etc. Footings for walls designed for 50% of live load. Free-standing columns designed for 80% of 100-lb load and 75% of 60-lb load. Wind-load 30 lb per sq ft for free-standing structures in built-up districts; 25 lb per sq ft at the 10th story and 2½ lb less for each lower story, and 2½ lb more for each higher story, until 35 lb is reached

Reduction in Assumed Loads. The building codes of various cities contain rules governing the assumptions to be made as to live loads and wind-loads, and these rules generally provide for some REDUCTION IN THE ASSUMED LOADS. Generally, it will be found possible to meet these requirements and at the same time arrange for the proper proportioning of the supporting areas. Table II, page 151, gives briefly the requirements of the building codes of several cities, as to assumed loads for office-buildings.

15. Proportioning the Supporting Areas for Equal Settlement

The Minimum Areas of Support. The actual dead loads and the assumed live loads and wind-loads for each linear foot of wall and for each column, pier, or other supporting element of the building down to the level of the footings having been calculated, a foundation-plan should be prepared giving the amount and center of action of all loads. For safety under the worst possible combination of loads, each footing should be ample to support the total of the dead loads, live loads and wind-loads coming on it. The MINIMUM AREAS OF SUPPORT for any footing are obtained by dividing the total of the dead loads, live loads and wind-loads by the safe supporting power of the foundation-bed. If the foundation-bed is rock, or can be considered as incompressible under the unit load, the minimum areas so obtained may be used for the footings. On compressible materials, or generally on all materials other than rock, the use of these minimum areas will not result in uniform settlements owing to the fact that the actual live loads and wind-loads are not consistent with the assumed live loads and wind-loads.

The Actual Loads on the Footings. In accordance with what has been previously said, let us assume that the dead load is constant, and that for a building under consideration the probable maximum live load is 50% of the assumed live load, that the probable maximum wind-load is 40% of the assumed wind-load, and that on the completion of the building, for a short period, the live loads and wind-loads reduce to zero. The ACTUAL LOADS ON THE FOOTINGS would then be:

(1) Upon completion of the building, the dead load only;

(2) Under the maximum load due to occupancy and to snow on the roof, the dead load plus 50% of the assumed live load;

(3) When loaded as in (2) and subject, in addition, to the maximum probable wind-action,

(*a*) The footings on the leaward side of the building will sustain the total dead load, plus 50% of the assumed live load, plus 40% of the assumed wind-load;

(*b*) The footings on the windward side of a building will sustain the total dead load, plus 50% of the assumed live load, minus 40% of the assumed uplift;

(*c*) Other footings will support the total dead load, plus 50% of the assumed live load, plus zero wind-load;

(4) Intermediate conditions as to live loads and wind-loads will produce loadings intermediate between (1) and (3).

Variations in Unit Loads on Foundation-Beds. With such known variations it is, therefore, impossible to proportion the supporting areas so that the unit load on the foundation-bed shall be uniform at all times. If the supporting areas are proportioned in the ratio of the dead load only, the building, on completion, and before occupancy, will uniformly load the supporting areas, and at that time all of the footings should show equal settlements; but subse-

quently, when the supporting areas have been subjected to the full effects of the live loads and wind-loads, certain supporting areas, having a high percentage of live loads, or of live loads and wind-loads, will be subject to a higher unit load, and the corresponding footings will consequently settle more than other footings supporting a low percentage of live loads, or live loads and wind-loads.

Non-Uniformity in Footing-Settlements. If, on the other hand, the supporting areas are proportioned on the basis of the dead loads, plus the maximum live loads, plus the maximum wind-loads, even if the MAXIMUM LOADS are the PROBABLE ACTUAL MAXIMUM LOADS, and not the FICTITIOUS ASSUMED LOADS, it is inevitable that upon the completion of the building and before occupancy, the supporting areas having a lower percentage of live loads and wind-loads will have a higher unit load, and the corresponding footings will have settled more than other footings supporting a high percentage of live loads and wind-loads. On this basis, the footings will not come to a uniform settlement until they have been subjected to the maximum live loads and wind-loads.

Arbitrary Rules for Proportioning Supporting Areas. Various ARBITRARY RULES have been recommended for the proportioning of the supporting areas to secure equal settlements. These rules generally provide for a reduction in the assumed live loads and wind-loads, but do not take into consideration the fact that a large proportion of the total settlement of certain footings may take place subsequently to the completion of the building and after other footings may have reached practically their full settlement.

Rational Rule for Proportioning Supporting Areas. The rule hereinafter recommended provides not only for a reduction of the assumed loads on a more rational basis, but also for the proportioning of the footings for the mean load, instead of for the ultimate load, and it is believed that the resulting settlements will be as nearly uniform as possible. The rule is based on the proportioning of the footings in accordance with the loads which will act on the footings at the time when all of the dead loads and one-half of the probable maximum live loads and wind-loads exist. The reason for taking one-half of the probable maximum wind-loads and live loads is that these loads vary from zero to a maximum, the average being one-half of the maximum.

Provision for Variations in Loads. On the completion of the building and before the live loads or wind-loads have gone on the footings, the settlements will not be uniform, because areas designed for a high percentage of live loads and wind-loads will have much less than their average load and will therefore have settled less than footings having a low percentage of live loads and wind-loads. When these same footings have been subjected to the maximum probable live loads and wind-loads, the settlements will again be unequal, because the areas have been proportioned for only one-half of the probable maximum live loads and wind-loads; but the footings which originally were the highest will now be the lowest. The inevitable movement due to the variation in the live loads and wind-loads will be equally divided, one-half of the settlement being required to bring the footing to the level of a footing having the dead loads only, and the other half of the settlement carrying it an equal distance below the same footing. In other words, the method provides for the least possible variation between footings having different proportions of live loads and wind-loads.

The Mean Load. For lack of a better name, the loads taken for the proportioning of the footings, consisting of the total dead loads, one-half of the probable maximum live loads and one-half of the probable wind-loads coming on each footing, will be called the MEAN LOAD.

The Mean Unit Load. The areas will be made such that the load on the foundation-bed due to the mean loads will be uniform, and this uniform load which, in general, will be considerably less than the allowable unit load on the foundation-bed will be called the MEAN UNIT LOAD.

The Minimum Unit Load. The necessity for providing for the worst possible condition of loading is satisfied if the supporting area for all footings is sufficiently large to support the total of the dead loads and the assumed live loads and wind-loads at the allowable unit pressure. The resulting areas of support are the MINIMUM AREAS, and any change in these areas necessary to make them proportionate to the mean loads must be effected by increasing some areas rather than by diminishing any. Any mean unit load which would give, when divided into the mean loads, areas, all of which would be larger than the minimum areas, would serve as the mean unit load, but it is more economical to determine the LOWEST POSSIBLE MEAN UNIT LOAD which, when applied to the mean loads, will give the least possible increase of the areas. This can be done by determining which one of the minimum areas carries the LEAST MEAN LOAD PER SQUARE FOOT. This area may be selected by calculating the mean load on each of the minimum areas, or more simply, by comparing the table of assumed loads and a table giving the mean loads, and noting which footing has the LARGEST PERCENTAGE OF REDUCTION between the assumed load and the mean load. The resulting mean load on this footing will be the MINIMUM UNIT LOAD which can be used as a MEAN UNIT LOAD.

The Method Reduced to Rule. The method can be reduced to rule as follows:

(1) Prepare a table giving in vertical columns or table-divisions for each footing, the dead loads, the assumed live loads, the assumed wind-loads and the total of these three loads. This table is called the TABLE OF ASSUMED LOADS.

(2) Prepare a similar table giving the dead loads, one-half of the maximum probable live loads, one-half the maximum probable wind-loads and the total of these three loads. This table will be called the TABLE OF MEAN LOADS.

(3) By a comparison of the two tables, find the supporting area which has suffered the greatest percentage of reduction between the total assumed loads and the total mean loads and find the unit load resulting from the mean load on this area. This unit load will be called the MEAN UNIT LOAD.

(4) Divide the total mean load as given in the table of mean loads for each footing by the mean unit load. The result will be the required AREA OF SUPPORT.

Short Method for Determining the Mean Unit Load. From the foregoing it follows that the MEAN UNIT LOAD can be obtained more directly by the following rule. Find the supporting area which has suffered the largest percentage of reduction between the total assumed load and the total mean load and multiply the allowable unit load on the foundation-bed by the ratio obtained by dividing the total mean load by the total assumed load.

Illustrative Example. The following example is figured out more fully than is necessary in practice in order to fully explain the method and also to compare the method with other methods frequently used and recommended. Ordinarily the wind-loads on a building of the size and type assumed in the example would be ignored, but they have been considered here to make the example complete.

A factory-building (Fig. 2) is to have four floors above the basement, each capable of supporting an assumed unit load of 200 lb per sq ft. The load on the flat roof is assumed at 50 lb per sq ft. The horizontal wind-pressure is assumed as a uniform pressure of 40 lb per sq ft, on the sides *AB* and *CD* only.

The vertical component of the wind-pressure is to be taken care of by the footings of the side walls. There is also an interior self-supporting chimney and ventilating shaft which is protected from the wind and which carries no floor-loads.

The foundation-bed is a uniform, sandy material which is expected to compress uniformly and at the rate of ½ in per ton of load per sq ft of supporting area.

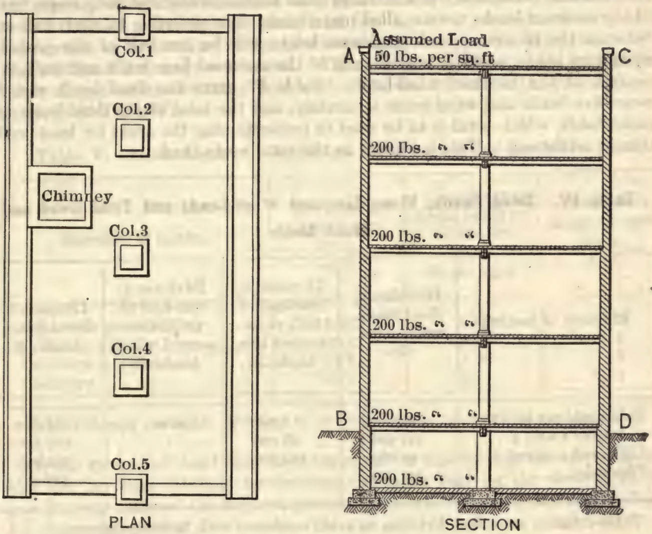

Fig. 2. Foundation-plan and Section of Factory-building

The MAXIMUM UNIT LOAD on the foundation-bed is taken at 4 tons, corresponding to a settlement of 2 in for the assumed load. The calculated dead loads of the building, including all construction down to the level of the footings, the summation of the assumed live loads and the vertical components of the assumed wind-loads are given in Table III.

Table III. Dead Loads and Assumed Live and Wind-Loads

Element of footing	Division 1, dead loads only, lb	Division 2, assumed live loads, lb	Division 3, assumed wind-loads, lb	Division 4, total dead, live and wind-loads, lb
Side walls per lin ft....	14 000	8 400	2 000	24 400
Columns 1 and 5......	137 500	160 000	....	297 500
Columns 2, 3 and 4....	90 000	340 000	....	430 000
Chimney.............	320 000	....	....	320 000

Table-columns are called divisions to avoid confusion with building-columns.

A careful study of the probable loading of the building shows that the maximum live loads at any one time will not exceed 60% of the total assumed live loads, and that the maximum wind-loads will be less than 50% of the assumed wind-loads, for the reason that the assumed wind-pressure is based upon the highest recorded pressure on a limited area in an exposed situation, whereas the proposed building will be in a sheltered situation. Having, therefore, determined the probable maximum live loads and wind-loads at 60% and 50% respectively of the assumed loads, the so-called mean loads, corresponding to loads half-way between the minimum and maximum loads, will be one-half of the probable maximum loads, or $60\% \times \frac{1}{2} = 30\%$ of the assumed live loads and $50\% \times \frac{1}{2} = 25\%$ of the assumed wind-loads. Table IV gives the dead loads and the mean live loads and wind-loads separately, and the total of the dead loads and mean loads, which total is to be used in proportioning the areas for least variation in settlement. This is known as the total mean load.

Table IV. Dead Loads, Mean Live and Wind-Loads and Total Dead and Mean Loads

Element of footing	Division 5, dead loads, unchanged, lb	Division 6, one-half of 60% of assumed live loads, lb	Division 7, one-half of 50% of assumed wind-loads, lb	Division 8, total mean loads, lb
Side walls per lin ft....	14 000	2 520	500	17 020
Columns 1 and 5......	137 500	48 000	....	185 500
Columns 2, 3 and 4....	90 000	102 000	....	192 000
Chimney..............	320 000	....	....	320 000

Table-columns are called divisions to avoid confusion with building-columns.

Comparing the two tables it will be seen that the interior columns of the building, columns 2, 3 and 4, had originally the largest percentage of live loads plus wind-loads, and have consequently suffered the greatest reduction in the amount of total load. The minimum areas of support for columns 2, 3 and 4, and also for the other elements of the footings, are obtained by dividing the total assumed loads given in division 4, Table III, by 8 000, the allowable unit load in pounds on the foundation-bed. The resulting areas are given in division 9, Table V. No reduction can be made in these areas without exceeding the limitation that the most disadvantageous combinations of loading, however improbable, shall not exceed the safe unit load. The adjustment of the areas to the probable mean loading, as given in Table IV, the table of mean loads, must be accomplished solely by increasing the sizes of certain footings.

If we divide the total mean loads in division 8, Table IV, by the minimum areas given in division 9, Table V, we will get the mean load per square foot on the minimum areas for each element of the footing. The results given in division 10, Table V, show that the mean load for columns 2, 3 and 4 is only 3 568 lb per sq ft, while under the chimney the load is 8 000 lb per sq ft. As no reduction in area is permissible it is necessary to increase the footings under the chimney, side walls and columns 1 and 5 until the mean unit load corresponds to the mean unit load for columns 2, 3 and 5. This is done by dividing the mean loads given in division 8, Table IV, by 3 568, the mean unit load as

determined for columns 2, 3 and 4. The resulting areas are given in division 11, Table V, and are the areas which should be used.

The method of calculation can be shortened and reduced to a rule as follows. Compare Table IV, the table of mean loads, with Table III, the table of assumed loads, and find the element of support which has suffered the highest percentage of reduction between the total assumed load and the total mean load, and note the corresponding minimum area of support at the allowable unit load on the foundation-bed. Divide the mean load for the same element of support by the number of square feet in the minimum area of support. The result will be the unit load for mean settlement. Then divide the mean loads for each element of support by the mean unit load. The results will be the required areas as given in Table V.

Table V. Mean Loads on Minimum Areas and Areas for Mean Loads

Element of footing	Division 9,* minimum areas, sq ft	Division 10, mean loads on minimum areas, lb per sq ft	Division 11, areas for mean loads, sq ft
Side walls per lin ft	3.05	5 580	4.7
Columns 1 and 5	37.2	4 986	51.9
Columns 2, 3 and 4	53.8	3 568	53.8
Chimney	40.0	8 000	89.7

Table-columns are called divisions to avoid confusion with building-columns.

Or the mean unit load may be determined by multiplying the allowable unit load by the ratio obtained by dividing the mean load for the element of support having suffered the highest percentage of reduction by the assumed load for the same element.

Resulting Settlements. The following Tables VI, VII and VIII show the comparative settlements which may be expected if the supporting areas are proportioned in accordance with different assumptions as to load. In all the tables it is assumed that the foundation-bed will settle ½ in per ton of load, and that the total assumed load will never load the foundation-bed in excess of 4 tons per sq ft.

In Table VI the footings are proportioned in the ratio of the DEAD LOADS only.

In Table VII the footings are proportioned in the ratio of the TOTAL ASSUMED LOADS.

In Table VIII the footings are proportioned in the ratio of the MEAN LOADS.

In each table, division 1 gives the dead load coming on the footings on the completion of the building. Division 2 gives the load coming on the footings when the building is subjected to the maximum probable live loads and wind-loads. Division 3 gives the supporting areas in accordance with the assumed loading. Division 4 gives the settlements for the unloaded building. Division 5 gives the settlement after the addition of the maximum probable live loads and wind-loads.

Explanation of Table VI. The method of proportioning the areas in the ratio of dead loads only, as recommended by C. C. Schneider* may, in the form of a rule, be stated as follows:

* See article on the Structural Design of Buildings, Trans. Am. Soc. C. E., vol. 54, June 1905.

Compare the table-division of dead loads, Table VI, with the division of assumed live loads, find the element of support which has the highest percentage of live loads to dead loads, and note the corresponding minimum area of support at the allowable unit load on the foundation-bed. Divide the dead load for the same element of support by the number of square feet in this minimum area of support, and the result will be the unit load due to the dead load only. Then divide the dead loads for all other elements of support by this unit load, and the results will be the areas required. Thus, in Table VI, it is seen by referring to Table III that columns 2, 3 and 4 have the greatest percentage of live load to dead load, and their minimum area of support, as in Table V, is 53.8 sq ft. Then, 90 000 ÷ 53.8 = 1 675 lb, the unit load due to the dead load only. The area for columns 1 and 5 is 137 500 ÷ 1 675 = 82.1 sq ft. The process is similar for the other elements.

Table VI. Footings Proportioned in the Ratio of the Dead Loads Only

Probable settlement where supporting areas are proportioned in the ratio of dead loads only					
Element of footing	Division 1	Division 2	Division 3	Division 4	Division 5
	Dead loads only, lb	Maximum probable loads, lb	Areas, sq ft	Settlements	
				Empty, in	Loaded, in
Side walls per lin ft......	14 000	20 040	8.3	0.42	0.60
Columns 1 and 5........	137 500	233 500	82.1	0.42	0.71
Columns 2, 3 and 4......	90 000	294 000	53.8	0.42	1.36
Chimney..............	320 000	320 000	191.0	0.42	0.42
Maximum variation, empty......................			....	0.00	....
Maximum variation, loaded......................			....	....	0.93

Table-columns are called divisions to avoid confusion with building-columns.

The calculations for settlements are readily made, when the amount of compressibility of the foundation-bed is known, by multiplying the unit load on the foundation-bed of each element of support by the amount of compressibility of the foundation-bed per unit of load. Thus, in the above example the amount of compressibility is given as ½ in per ton. In Table VI the unit loads, due to dead loads for each element of support, are the same, or 1 675 lb = 0.838 tons per sq ft, which, multiplied by ½ = 0.42 in. Similarly, the unit loads due to maximum probable loads for each element of support are determined, and these loads, in tons, multiplied by one-half, give the settlements in inches as given in division 5 of Table VI.

Explanation of Table VII. The areas given in Table VII are obtained by dividing the total maximum dead loads, live loads and wind-loads by the allowed unit, 8 000 lb per sq ft, and are the minimum areas given in Table V. The settlements for the loaded building are based on the maximum probable loads as given in division 2 of Table VII.

Table VII. Footings Proportioned in the Ratio of the Total Assumed Loads

Probable settlement where supporting areas are proportioned in the ratio of total assumed loads					
	Division 1	Division 2	Division 3	Division 4	Division 5
Element of footing	Dead loads only, lb	Maximum probable loads, lb	Areas, sq ft	Settlements: Empty, in	Settlements: Loaded, in
Side walls per lin ft	14 000	20 040	3.1	1.13	1.61
Columns 1 and 5	137 500	233 500	37.2	0.92	1.57
Columns 2, 3 and 4	90 000	294 000	53.8	0.42	1.36
Chimney	320 000	320 000	40.0	2.00	2.00
Maximum variation, empty			....	1.58	....
Maximum variation, loaded			....	....	0.64

Table-columns are called divisions to avoid confusion with building-columns.

Table VIII. Footings Proportioned in the Ratio of the Mean Loads

Probable settlement where supporting areas are proportioned in the ratio of total mean loads					
	Division 1	Division 2	Division 3	Division 4	Division 5
Element of footing	Dead loads only, lb	Maximum probable loads, lb	Areas, sq ft	Settlements: Empty, in	Settlements: Loaded, in
Side walls per lin ft	14 000	20 040	4.7	0.74	1.06
Columns 1 and 5	137 500	233 500	51.9	0.66	1.12
Columns 2, 3 and 4	90 000	294 000	53.8	0.42	1.36
Chimney	320 000	320 000	89.7	0.89	0.89
Maximum variation, empty			....	0.47	....
Maximum variation, loaded			....	....	0.47

Table-columns are called divisions to avoid confusion with building-columns.

Explanation of Table VIII. The areas in Table VIII are obtained as already explained and as given in division 11, Table V, and the methods used in determining the settlements are similar to those used for the preceding tables. In Table VIII it will be noted that columns 2, 3 and 4 have a settlement of $1.36 - 0.42 = 0.94$ in, as a result of the addition of the live loads and wind-loads. Half of this settlement is required to bring these footings down to the level of the chimney-footing, and the other half of the settlement brings

them below the chimney-footing. There is no way to prevent this settlement of 0.94 in, but its effect on the building is reduced to a minimum by having the settlement of the footings of columns 2, 3 and 4 start above the chimney-footing and finish below it. The chimney-footing does not change its elevation after the completion of the building, and compared with it, the variation in level of the other footings is the minimum. In their mean position, half-way in their movement, these other footings will be at the same level as the chimney-footing.

16. Determining the Supporting Areas

General Requirements. In laying out the AREAS OF SUPPORT for any structure it should be borne in mind, as previously explained, that (1) the total of the dead loads, assumed live loads and assumed wind-loads should not load the foundation-bed in excess of the allowable load on it; (2) when the foundation-bed is compressible the areas of support should be calculated by the method of mean loads; and (3) the center of gravity of the supporting area should coincide with the center of action of the load to be supported. To these may be added a further condition that (4) economy will be furthered by keeping the supporting areas simple in outline and by arranging each area as compactly as possible around the center of the load to be supported.

(1) The first condition is necessary in order to provide that no possible condition of loading will exceed the allowable pressure on the foundation-bed.

(2) The second condition provides for making the settlements of different footings as nearly equal as possible.

(3) The third condition provides that the settlements of each footing shall be uniform, that is, that the footing shall not settle out of level.

(4) The fourth condition provides for economy in design in the footing itself and for economy in making the excavation for the footing, especially in the case of deep excavations requiring sheathing for the protection of their sides.

In the case of a free-standing structure, the total load of which is not in excess of the supporting capacity of the entire area of the building at the safe unit load on the foundation-bed, it will generally be possible to arrange simple supporting areas whose centers will correspond with the centers of the loads. The disposition of such areas is considered in succeeding paragraphs in the discussions of CONCENTRIC LOADING. In buildings having restricted sites, where walls or columns are placed close to adjoining property-lines, it will frequently be impossible to arrange for simple concentric loadings and necessary to use offset footings, cantilevers or other devices to transfer the loads to supporting areas located on the property. Such supporting areas are discussed in succeeding paragraphs relating to ECCENTRIC FOOTINGS.

Footings with a Concentric Load. In order to have the load on the foundation-bed uniform under a footing it is necessary that the center of gravity of the supporting area should coincide with the center of gravity of the load, otherwise the area is said to be ECCENTRICALLY LOADED and the resulting load on the foundation-bed will not be uniform. Any variation in the loading of a compressible foundation-bed under a footing will result in an unequal settlement of the footing and this in turn will result in unequal stresses in the wall, pier, or column supported by the area.

Wall-Footings with Concentric Load. In the case of a WALL, the footing should project an equal distance on each side so that the center of gravity of the supporting area will coincide with the center of gravity of the wall and of the loads transmitted by the wall. The width of the supporting area should vary with the load on the wall, irrespectively of any change in the thickness of the wall

Footing for a Concentric Isolated Load. In the case of a SIMPLE CONCENTRATED LOAD, as, for example, a load from a COLUMN OR PIER, the footing may be CIRCULAR, SQUARE, RECTANGULAR, OR IRREGULAR in outline, but the center of gravity of the area must coincide with the center of gravity of the load. Theoretically the CIRCULAR SHAPE gives the most economical footing, as the supporting areas extend radially the least possible distance from the center or axis of the load. Where deep excavation is necessary the circular form may lend itself to an economical method of excavation, as, for example, when cylindrical piers are sunk by the pneumatic method or by dredging. In general, however, for ordinary footings the RECTANGULAR FORM is preferable, in that it lends itself to an economical arrangement of grillage-beams. The SQUARE is the most economical rectangle as the sum of the bending movements in the grillage and bolsters is reduced to a minimum.

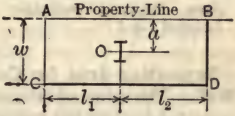

Fig. 3. Elongated Supporting Area. Concentric Load

Elongated Supporting Areas. When the supporting area for an isolated load cannot be made a circle or a square, for example, when the square or the circle would overlap an adjoining property-line or interfere with an adjoining supporting area, the necessary area may frequently be made RECTANGULAR in form, as $ABDC$ (Fig. 3), having a width w, twice the distance a between the center of the load O and the limiting line AB.

The required length l equals the required area divided by w and the area should be centered on O, that is, l_1 must equal l_2.

Combinations of Simple Areas. Two Adjacent Isolated Areas. When adjoining supporting areas overlap or when, for other reasons, it is desirable to COMBINE ADJACENT FOOTINGS, the best arrangement may be obtained as follows: Knowing the supporting area required for each of two adjacent concentrated loads and the distance between the centers of the loads, the sum of the two areas should be divided by twice the distance between the load-centers. The quotient will be the width or the dimension of the required rectangle of support taken at right-angles to the line connecting the load-centers; and the other dimension of the rectangle will be twice the distance between the load-centers. The center of the area should be placed so as to coincide with the center of gravity of the two loads, when it will be found that each load will be concentric with its own area of support. Where a row of columns requires areas which nearly overlap, the COMBINATION OF THE AREAS frequently results in economy in excavation and form-work.

Supporting Area for a Concentrated Load in the Line of a Wall. If one or more concentrated loads are carried in the line of a wall the ADDITIONAL SUPPORTING AREAS required for such concentrated load may be provided in either of two ways.

(1) If the concentrated loads rest on the wall, as, for example, when the wall supports the ends of girders and when the conditions are such that the concentrated loads are distributed along given lengths of it, then, all that is necessary is to increase the width of the footing for the given lengths sufficiently to provide for the total of the uniformly distributed and concentrated loads.

(2) If a concentrated load is on the center line of the wall but cannot be distributed by the wall, as when a considerable load is carried by a pier or column to the level of the footings, then one-half the additional area for the concentrated load should be placed on either side of the wall-footing, so that a line connecting the centers of the two areas will pass through the center of the load. In general,

it is desirable that the additional areas, together with the area for the wall lying between them, should APPROXIMATE A SQUARE. Knowing the width of the footing required to support the wall and the additional area required to support the concentrated load, the length of the side of the required square can be determined by the following formula (Fig. 4):

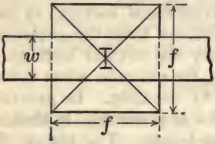

Fig. 4. Square Supporting Area. Wall and Concentric Isolated Load

Let w = the width of the footing;
A = the area required to support the concentrated load;
f = the side of the square which will support a length of wall equal to f, and also provide an additional area equal to A. Then

$$f = \tfrac{1}{2} w + \sqrt{A + \tfrac{1}{4} w^2}$$

Supporting Area for Concentrated Load not in the Center Line of a Wall. The same additional supporting area is required for this as for a concentrated load on the center line of a wall, but the total area must be divided unequally between the two sides of the wall-footing, the larger portion being placed on the side of the eccentric load. The simplest way to determine the location of the supporting areas for this combination is to determine the size of the required square as if the concentrated load were concentric with the center line of the wall. The next step is to calculate the load due to the wall for the length of this square and determine the location of the center of gravity of the combined loads, that is, the center of gravity of this wall-load and the concentrated load. The center of the supporting area is then placed concentrically with the center of gravity of the combined loads. In Fig. 5 let

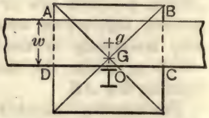

Fig. 5. Square Supporting Area. Wall and Eccentric Isolated Load

w = the required width of the wall-footing;
O = the concentrated load;
A = the area required for the support of the concentrated load. Then, as before, the length of the side of the required square will be

$$f = AB = \tfrac{1}{2} w + \sqrt{A + \tfrac{1}{4} w^2}$$

The center of gravity of the wall-load contained between the lines AD and BC is at g, and the amount of the load is evidently the load per foot multiplied by the distance $AB = f$. Knowing the position and amount of the loads at O and g, the center of gravity of the combined loads is determined, say at G. This fixes the center for the square.

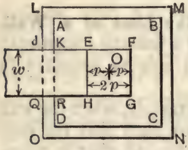

Fig. 6. Square Supporting Area. Isolated Load on End of Wall

Supporting Area for a Concentrated Load on the End of a Wall. A somewhat different treatment is required for this, but the supporting area may be best determined as follows (Fig. 6): Knowing the width w of the footing required for the support of the wall, the additional area required for the concentrated load O and the distance p from the center of the concentrated load from the end of the wall, proceed in this way. Determine the square whose area corresponds to the sum of the areas required for the support of the concentrated load and for a length of wall equal to twice the projection of the wall beyond the center of the concentrated load. Plot this square $ABCD$ on the

foundation-plan and also the total area required for the support of the wall. The square $ABCD$ includes an area sufficient for the support of the concentrated load and for a section of the wall $EFGH$ corresponding to a length of wall equal to twice the projection p, multiplied by the width of the footing. It is evident that the area $KEHR$ is loaded both by the wall and the concentrated load; in other words, that the square $ABCD$ is too small by the amount of the rectangle $KEHR$. The required square $LMNO$ will be approximately the square which will contain the original area $ABCD$ plus the area $KEHR$, plus twice the area $JKRQ$. The length of the side $LM = MN$ will be approximately the length of the original square plus one-half of the area $KEHR$ divided by the length of the original square. The resulting square should be moved from the position shown on the drawing so that its center coincides with the center of gravity of the combined concentrated load and the wall-load back as far as the square goes on the wall. A further approximation may be necessary where accuracy is required. The final result should be that the area of the square $LMNO$ should be sufficient to support the concentrated load O and that portion of the wall-load $JFGQ$ resting on the square, and that the center of gravity of the square should coincide with the center of gravity of the combined loads.

17. Offset Footings

Supporting Areas for Non-Concentric Loads. When walls, columns, or piers are placed close to property-lines the required supporting areas cannot be placed concentrically with the loads without overlapping the property-lines. In such cases recourse must be had to some method which will transfer the loads to supporting areas not concentric with the loads. An attempt to accomplish this result, the method known as OFFSETTING THE FOOTING has been largely used, especially for side walls adjoining property-lines. While theoretically faulty, if not useless, it is indisputable that OFFSET FOOTINGS have generally served the purpose for which they were designed. In the typical construction a cellar wall rests on a course of concrete or of flat stones forming a footing course considerably wider than the wall, the projection being entirely on one side of the wall. The load acting on one side of the center of the footing loads the supporting area unequally. The VARYING LOAD on the supporting area can be calculated as follows: In Fig. 7 let

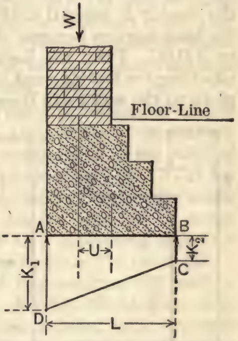

Fig. 7. Offset Footing. Varying Pressure on Foundation-bed

W = the total load per unit of length coming on the supporting area;
U = the eccentricity of load, that is, the distance between the center of the load and the center of the supporting area;
L = the width of the footing = the width of the supporting area = AB;
K_1 = the unit load, or pressure on the foundation-bed at A, the edge of the footing nearest the load;
K_2 = the unit load, or pressure on the foundation-bed at B, the edge of the footing farthest from the load;
y = any ordinate, from A to B.

Then the AVERAGE PRESSURE on the foundation-bed will evidently be W/L. The pressure at A, the edge nearest to the point of application of the load, will

be $K_1 = W/L\ (1 + 6\ U/L)$, or the MAXIMUM LOAD will equal the average load plus six times the average load multiplied by the ratio of the ECCENTRICITY divided by the width of the footing.

Similarly, the pressure at B, the edge farthest from the point of application of the load, will be $K_2 = W/L\ (1 - 6\ U/L)$, or the MINIMUM LOAD equals the average load minus six times the average load multiplied by the ratio of the eccentricity divided by the width of the footing.

When the ECCENTRICITY equals 1/6 the width, the pressure at B becomes zero. If the eccentricity exceeds 1/6 the width there will be an uplift at B, or the footing will have a tendency to overturn. This relation is generally expressed by saying that to avoid an upward reaction the center line of the load must fall within the MIDDLE THIRD of the base.

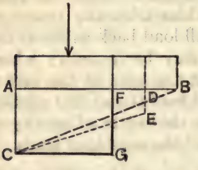

Fig. 8. Pressure-diagrams for Footings

Load-Diagrams for Offset Footings. If in the diagram (Fig. 8) the figure $ADEC$ represents the load-diagram on the foundation-bed for a width of footing AD and the load AC is the maximum permissible load, then the area $ADEC$ represents the maximum support afforded by the footing AD. If the width is increased until the load falls on the limit of the middle third or to the width AB, then the load at B is zero and the support is represented by the triangle ABC, the area of which is less than the area $ADEC$. Moreover, if the width of the footing is reduced until its center is concentric with the load-center, then the load-diagram becomes $AFGC$, the area of which is greater than either ABC or $ADEC$. From the foregoing it is evident that any advantage gained by offsetting the footing must be obtained at the cost of concentrating the support given to the wall away from the center line of the wall.

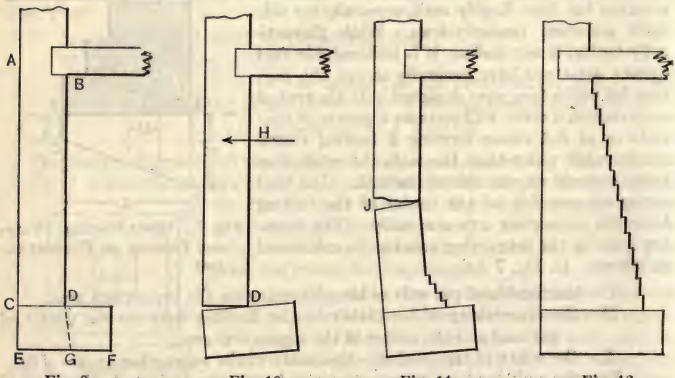

Fig. 9 Fig. 10 Fig. 11 Fig. 12

Figs. 9, 10 and 11. Eccentric Loading and Tendencies to Failure Due to Offset Footings; Fig. 12. Improved Type of Construction

Eccentric Loading Due to Offset Footings. In Fig. 9, representing a simple case of ECCENTRIC LOADING due to OFFSET FOOTINGS, the load on the foundation-bed at E is perhaps twice the average load and at F about zero. Under these conditions the projecting portion of the footing may shear, as indi-

cated, along the line DG. If it does not shear and if there is any settlement due to the load, the settlement will be unequal and the footing course will tend to rotate into the position shown in Fig. 10. The entire load will then be transmitted through the inner lower corner D of the cellar wall, rendering the wall unstable and developing a tendency to move in the direction H.

The cellar wall may successfully resist this tendency by its own rigidity assisted by the first-floor beams acting as ties or by the external resistance afforded by an abutting wall or bank of earth, or it may partially or completely fail, developing a horizontal crack as indicated in Fig. 11 at J.

In this figure it will be noted that the base of the wall itself is offset. This is done to prevent the separate rotation of the footing course; but this construction does not diminish the TENDENCY TO ROTATION of the entire base of the wall and to the formation of a crack at J.

An improved type of construction is illustrated in Fig. 12, in which the floor-beams are anchored into the wall and the cellar wall has a continuous stepped batter from the level of the footing up to the level of the beams. The beams should evidently be arranged as tension-members, should run across the building and should be anchored in the opposite wall. While this method may have some effect it is of doubtful efficacy and should never be used for piers.

18. The Use of Cantilevers in Foundations*

Application of the Principle of the Lever. The use of the CANTILEVER, in transferring a load to a supporting area not concentric with the load, is based upon the PRINCIPLE OF THE LEVER and involves a girder or cantilever connecting the two loads, and a supporting area or areas the CENTER OF ACTION of which lies between the two loads. Part or all of the load on one side counterbalances the load on the other side of the center of the supporting area.

Illustrative Example. If an exterior column A (Fig. 13) carrying a load of 400 tons and requiring 100 sq ft of supporting area, at 4 tons per sq ft, the column-center being 18 in from a property-line PP which forms the limit of the building plot, it is evidently impractical to employ a concentric footing 3 by 33⅓ ft for its support. If, however, a sufficient counterweight can be found in the shape of an adjacent interior column-load, as at B, the exterior load can be transferred by a girder or cantilever construction $CDEF$ to a supporting area MN lying between the two loads, and entirely within the limits of the property.

In Fig. 13 let PP represent the property-line, A the center of the load on column A, and B the center of the load on column B. Let the load on A be 400 tons, on B, 200 tons and the distance AB between centers, 20 ft. Assume that a rigid girder $CDEF$ supports and connects the two columns. If now a FULCRUM or point of support G is provided for the girder at some point between A and B, the load on that point can be readily determined from the PRINCIPLE OF THE LEVER by multiplying the load on A, 400 tons, by the distance AB, 20 ft, and dividing the product by the distance BG, 19 ft; or, the load on $G = 400 \times 20/19 = 421$ tons +. The area required for the support of this load, at 4 tons per sq ft, is $421/4 = 105\frac{1}{4}$ sq ft. The uplift at B, or the part of the load B required to counterbalance the overhanging load A is, from the principle of the lever, the product of the load A by the lever-arm AG divided by the lever-arm BG. The load on the footing for B is the difference between the original load and the uplift; but in view of the possibility of a reduction in the load A, which would decrease the uplift at B, it is well to provide for a possible increase in the load B.

*** See, also, Chapter XIX, pages 678 to 680, for an example of a Continuous Girder in Grillage Foundation.**

Determination of the Area of Support. In determining the AREA OF SUPPORT for A, having assumed one dimension of the supporting area to be twice the distance GP, or say 5 ft, the other dimension will be 105¼ sq ft/5 = 21 ft ½ in. If the length 21 ft ½ in, as determined, is found to be excessive, then

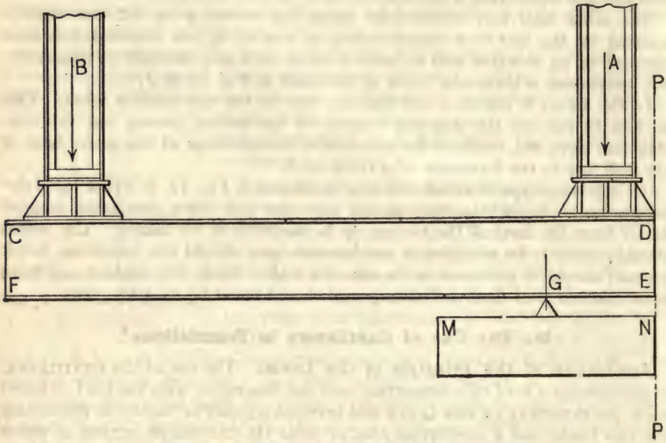

Fig. 13. Cantilever Foundation-construction

the point G must be moved to the left and the corresponding length of the supporting area must be determined as before. When the length of the supporting area for the fulcrum of the cantilever is limited, so that the length parallel to the property-line is fixed, the width of the area can be determined experimentally or by the use of the formula

$$X = (L + u) - \sqrt{(L + u)^2 - 2\,WL/lS}$$

in which

L = the distance between centers of the two loads;
W = the load nearest to the property-line;
l = the length of the supporting area;
S = the unit load on the supporting area; and
u = the distance between the center of action of the load to be cantilevered and the edge of the supporting area nearest to the property-line.

If the position of the center of gravity of the load A combined with that part of the load on B which is borne by the cantilever is determined, it will be found to coincide with the fulcrum or point of support G of the cantilever, thus demonstrating that the use of the cantilever provides a means of combining two loads so that their center of gravity falls on the center of a supporting area not concentric with either load.

The Grillage Fulcrum. Of course in practice the KNIFE-EDGE FULCRUM shown in the diagram is not used. The bottom flange of the girder forming the cantilever rests on the DISTRIBUTING GRILLAGE directly, as is shown in Fig. 14, which may be considered a typical arrangement.

The Girdering-Method for Two Equal Loads. When it is desirable to support two or more adjacent concentrated loads on a single supporting area

the method called GIRDERING is employed. In the case of two concentrated loads, let A and B (Fig. 15) represent two columns. Let W_1 represent the load on A and W_2 represent the load on B. Let D represent the distance between the centers of the two loads. Let G represent the center of gravity of the combined loads. Let r represent the allowable unit load on the foundation-bed. The required area of support will be $(W_1 + W_2)/r$. This area may be of any

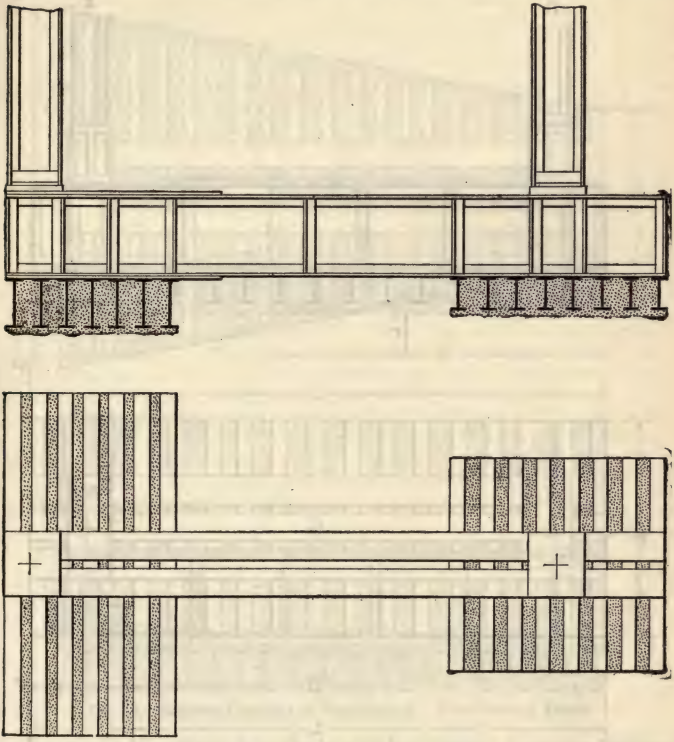

Fig. 14. Cantilever Foundation. Grillage Fulcrum

desired shape, provided that its center of gravity coincides with the center of gravity of the combined loads at G. In general, however, the most economical arrangement will result when each load is as nearly as possible over the center of gravity of its own required area. If, however, this is impracticable, as for example, when either column is near a property-line or an adjoining footing, it will be necessary to distribute the loads of both columns over the area lying between the two columns. In the case of two columns equally loaded, as in Fig. 15, the distance u, from the center of column A to the property-line PP, determines the maximum allowable extension beyond column A. The dimensions of the area are obtained by making the length L of the footing equal to

the distance D between the columns plus twice the extension u. Knowing the length of the required area the width w is determined by simple division.

The Girdering-Method for Two Unequal Loads. In the case of columns not equally loaded, the SUPPORTING AREA may be a TRAPEZOID, as in Fig. 16, the center of gravity of which must coincide with the center of gravity of the two loads. Knowing the sum of the two loads and the required area for their

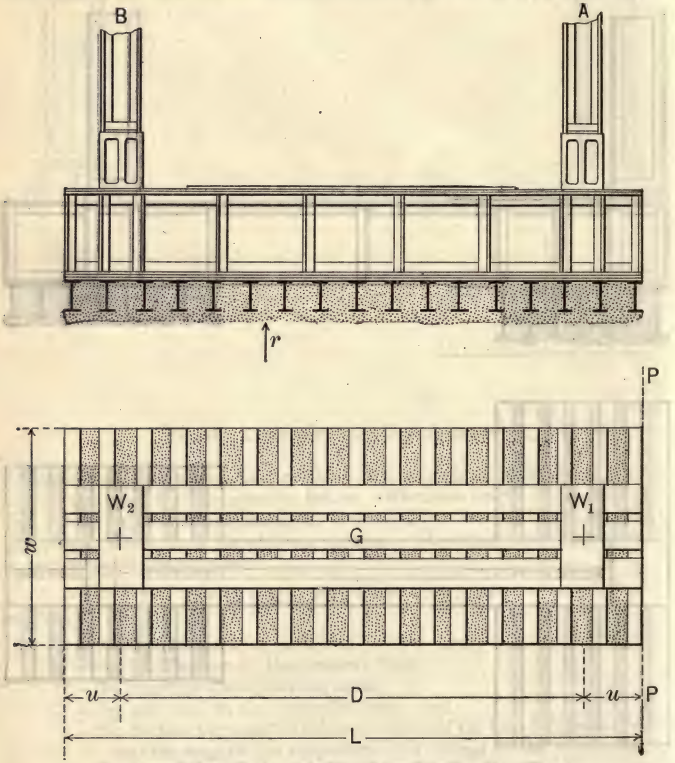

Fig. 15. Girdering-method of Foundations. Two Equal Loads

support, and fixing the total length L of the footing in accordance with the requirements that the footing shall not project beyond the line PP, the widths of the footing at the small and large end, a and b respectively, can be determined as follows: Let B represent the distance from the small end of the trapezoid to the center of gravity of the two loads and let A represent the area of the trapezoid. Then

$$b = 2\,A/L\,(3B/L - 1)$$

and

$$a = 2\,A/L\,(2 - 3\,B/L)$$

also $\qquad A = (a + b)\,L/2 \quad \text{and} \quad a + b = 2\,A/L$

Cantilevering an Exterior Wall. In the case of a wall the same principles apply, but the cantilevering effect must be distributed along the length of the wall. This can be accomplished by placing a girder under the wall, the girder in turn resting on the cantilever, or by using a number of cantilevers arranged

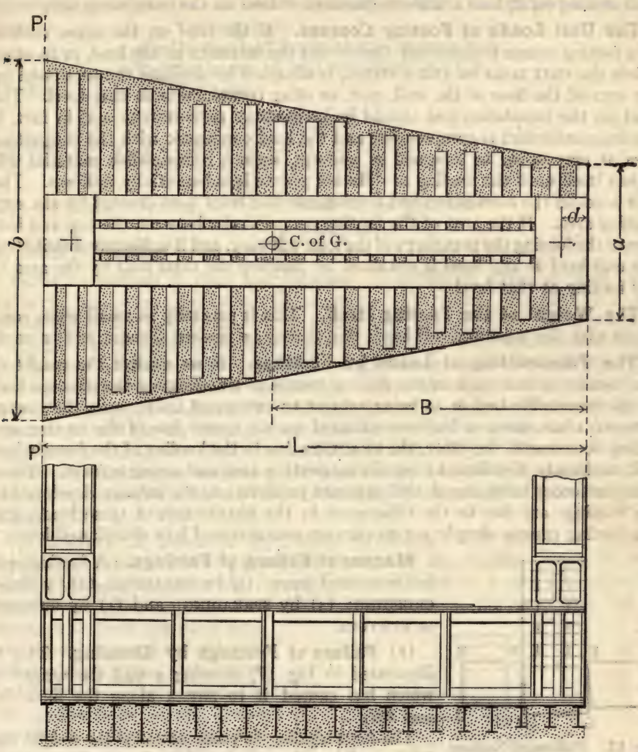

Fig. 16. Girdering-method of Foundations. Two Unequal Loads

in fan shape and radiating from the interior load-center. In narrow buildings the cantilevers may run from wall to wall.

Double Cantilevering. The considerations controlling the design of the supporting areas required are the same as outlined in the preceding paragraphs.

19. Stresses in Footing Courses

Size and Form of Footing Courses. The footing courses of all walls and piers should be larger than the superimposed construction in order to secure STABILITY AGAINST OVERTURNING and to reduce the UNIT LOAD on the foundation-bed. When the change in size is accomplished abruptly as when a wall rests on a grillage or a slab of plain or reinforced concrete the footing is called a SPREAD FOOTING. When the base of the wall is thickened by means of offset

courses so that its bottom course is substantially as large as the footing course the construction is known as a STEPPED FOOTING. It is evident that no hard and fast line can be drawn between the two classes. Whatever the form of the footing is it must be strong enough to distribute the more or less concentrated load coming on it, into a uniform pressure or load on the foundation-bed.

The Unit Loads of Footing Courses. If the load on the upper surface of a footing course is uniformly distributed the intensity of the load, or in other words the UNIT LOAD ON THE FOOTING, is obtained by dividing the total load by the area of the base of the wall, pier, or other construction at that level. The load on the foundation-bed should be UNIFORMLY DISTRIBUTED and in fact, if the foundation-bed is compressible and the load concentric with the supporting area, it may safely be assumed as uniform, since a compressible material will adjust itself until the loading at different points is substantially uniform. The unit load on the foundation-bed is evidently the total load divided by the supporting area. If the area of the footing course varies between the top and bottom of the footing the INTENSITY of the load will vary, and if uniformly distributed, the unit load at any level is obtained by dividing the total load by the area of the footing at that level.

The Weight of the Footing Itself. This is generally so small when compared with the superimposed loads that it may be ignored without serious error.

The Transmitting of Loads by Footings. If we neglect the weight of the footing we can consider the footing course as transmitting the imposed load to the foundation-bed or as being subject to two equal loads; one, the SUPERIMPOSED LOAD, more or less concentrated on the center line of the footing and acting downward; the other, the REACTION due to the loading of the foundation-bed, uniformly distributed over the supporting area and acting upward. These loads or forces being equal and opposite in direction, the stresses developed in the footings are due to the differences in the distribution of these loads, and the footing courses simply act to convert concentrated into distributed loads.

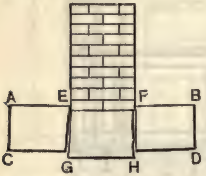

Fig. 17. Failure of Footing by Shearing

Manner of Failure of Footings. A footing may fail in several ways: (1) by SHEARING; (2) by direct CRUSHING; (3) by SPREADING; and (4) by BENDING or RUPTURE.

(1) Failure of Footings by Shearing. This is illustrated in Fig. 17, showing a wall the weight of which has caused it to SHEAR along the lines *EG* and *FH*.

The force tending to cause SHEAR is the weight due to the wall less the reaction of the foundation-bed acting on the under side of the section *EFGH*. Since the load is supposed to be uniformly distributed this is equivalent to the product of the area corresponding to the width *CD* minus the width *GH* times the length of the wall considered, by the unit loading on the foundation-bed.

For a 1-ft length of wall the force causing shear, S, is

$$S = W\,(l - w)/l$$

in which W = the load due to wall per foot of length in pounds;
l = the width of footing;
w = the width of base of wall.

Or, since

$W/l = U$ = the unit load on the foundation-bed in pounds per square foot,
$S = U\,(l - w)$

Since U is in terms of feet, l and w also must be in feet. The resistance to shear, R, under the conditions illustrated in Fig. 17, taken for a 1-ft length b of the wall, is determined by the equation

$$R = 2 \times d \times b \times f$$

in which f = the safe resistance of the material to shear, in pounds per square inch;
d = the depth of the footing in inches; and
b = the length of wall considered = 12 in.

Placing $S = R$, we have

$$2\,dbf = U\,(l - w)$$

Or, since $(l - w)/2$ = the projection of the footing

$$UP = 12\,df$$

The depth of the footing, therefore, must not be less than

$$d = UP/12f$$

in which P is in feet.

Shear in Footings of Piers and Columns. FAILURE BY SHEAR is most likely to occur in footings for piers and columns. The FORCE TENDING TO CAUSE SHEAR is the total load on the column or pier less the reaction of the foundation-bed on the area immediately under the column-base. The resistance offered is determined by multiplying the perimeter of the column-base by the depth of the footing and by the allowable unit shear. When the area of the column-base is small, the entire load may be taken as producing shear. When reinforced concrete is used for the footing, there must be a sufficient number of stirrups to take care of the shear. (See Chapters XXIV and XXV.) Where steel beams are employed the cross-section of the beams must be sufficient to take care of the shear, otherwise additional web-plates should be added, as is explained in Chapters XV and XX.

(2) **Failure of Footings by Direct Crushing.** The failure of footings by DIRECT CRUSHING of the materials composing the footings rarely, if ever, occurs. Where, however, the concentrated load, due to a pier or column, is distributed by beams or girders which have thin webs, the webs may fail by BUCKLING. Such beams or girders should have their webs reinforced by vertical STIFFENERS or by additional WEB-PLATES, and the spaces between the beams or girders should be filled with concrete or grout. Where the load transmitted by the column-base exceeds the safe unit load on the material of the footing the area of the column-base may be increased, or a block of granite may be interposed between the concrete or masonry footing and the base of the columns. In this case, however, such granite blocks should be considered as a footing course and designed to resist bending, by formulas hereinafter given.

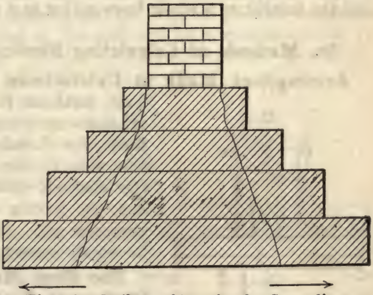

Fig. 18. Failure of Footing by Spreading

(3) **Failure of Footings by Spreading.** Failure of the footings by SPREADING may occur under walls or piers, as shown in Fig. 18, especially when the

foundation-bed is of clay or other yielding material, which has, under the load of the footing, a tendency to FLOW along the lines indicated by arrows in the figure. This tendency should be provided against by making the bottom layer continuous and adequate to resist the tension. Vertical joints, such as are made in footings composed of masonry, are sources of weakness, and should be avoided. The TENDENCY TO SPREAD is greatest in footings having a spread which is wide compared with the width of the superimposed wall or other construction. The writer knows of at least one important footing which has failed in this way, the cracks in general following the joints of the masonry substantially as shown in Fig. 18.

(4) **Failure of Footings by Bending or Rupture.** A footing may fail by BENDING OR RUPTURE as a beam or girder. In the case of a wall, if the footing bends, as shown in Fig. 19, the concentration of the load on the lower edges

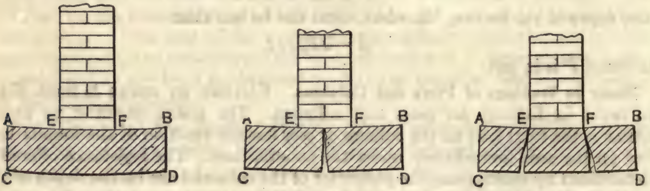

Fig. 19 Fig. 20 Fig. 21

Figs. 19, 20 and 21. Failures of Footings by Bending

of the wall, as at E and F may cause the base of the wall to fail. This possibility should be borne in mind in designing footings where the load on the wall approaches the allowable unit load for the material composing it, and especially where the width of the footing is much greater than its own width. If the footing fails by RUPTURE the rupture may occur either under the center line of the wall, as in Fig. 20, or at points close to the outer edge of the wall as in Fig. 21. Fig. 20 illustrates the objection to using a footing course composed of masonry or stones which do not extend the full width of the footing. The joints in such construction prevent the footing course from acting in TENSION and the footing as a whole from acting as a BEAM.

20. Methods of Calculating Bending-Stresses in Wall-Footings

Assumptions Made in Determining Bending-Stresses in Footings. Two methods for the calculation of the BENDING-STRESSES IN FOOTING COURSES are in general use. Both are based upon the assumption that the REACTION of the foundation-bed is UNIFORM; but the methods differ in the assumption made as to how the footing course and the base of the superstructure act. Neither assumption can be held to be wholly correct.

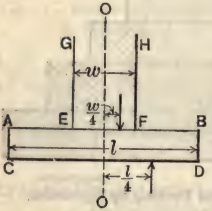

Fig. 22. Bending-stresses in Footings. First Method

The First Method of Determining Bending-Stresses in Footings. This method is based upon the assumption that the pressure of the wall on the footing is uniform over the area and remains so at all times.

If, in Fig. 22, $ABCD$ represents a footing course supporting a centrally located wall $EFGH$, and if

W = the load of the wall in pounds per linear foot;
w = the width of the wall in feet;
and l = the width of the footing in feet;
then
$\frac{1}{2}(l-w)$ = the projection AE or FB,
and $W/l = U$ = the unit load per square foot on the foundation-bed.

Considering the forces acting on the right of the center line of the wall for a 1-ft length of wall, it is evident that the uplift on the half-footing OD will equal $\frac{1}{2} W$ and that its CENTER OF ACTION will lie half-way between O and D, or at a distance $\frac{1}{4} l$ from the center line OO; and, similarly, that the load due to one-half the wall will be $\frac{1}{2} W$ and that its CENTER OF ACTION will be at a distance $\frac{1}{4} w$ from the center line OO. The resulting moments will be

$$M_1 = \tfrac{1}{2} W \times \tfrac{1}{4} l = \tfrac{1}{8} Wl$$

and

$$M_2 = \tfrac{1}{2} W \times \tfrac{1}{4} w = \tfrac{1}{8} Ww$$

and as these two moments act in opposite directions, the resultant moment tending to produce bending in the footing will be the difference between the two, or the bending moment at the center line OO is

$$M_0 = M_1 - M_2$$

or

$$M_0 = \tfrac{1}{8} W (l - w)$$

Or, since

$$W/l = U \quad \text{and} \quad \tfrac{1}{2}(l - w) = P, \text{ the projection,}$$

Equation (1) may be written in either of the forms

$$\left.\begin{array}{l} M_0 = \tfrac{1}{8} U (l - w) l \\ \text{or} \quad M_0 = \tfrac{1}{4} WP \end{array}\right\} \qquad (1)$$

The Error Involved in this first method is due to the assumption that the pressure on the upper surface of the footing remains UNIFORMLY DISTRIBUTED, as if the base of the wall acted as a FLUID, in which case the distribution of the load would remain constant and the formula would be correct. But the base of the wall is not a FLUID, but a SOLID which will resist DEFORMATION. If, as in Fig. 19, the footing course $ABCD$ deflects and the base of the wall is assumed to be incompressible, the entire load of the wall will be communicated to the footing through the edges E and F. While such a concentration is, of course, impossible (as the edges E and F will crush or compress until a considerable area of the base of the wall is in contact with the footing) the result is that the weight of the wall is concentrated near the outer edges of its base. Equation (1) gives results which are too large; but as it errs on the side of safety, it is recommended for general use.

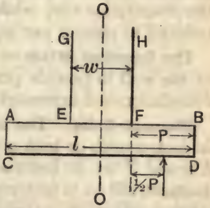

Fig. 23. Bending-stresses in Footings. Second Method

The Second Method of Determining Bending-Stresses in Footings, also in common use, takes into consideration only the projecting portion of the footing as follows:

If in Fig. 23 $ACBD$ represents a footing course supporting a centrally located wall $EFGH$, and if we use the notation of the preceding method, then, if we assume that the footing acts as a FIXED BEAM and the projections AE and FB as CANTILEVERS rigidly supported by the wall, and denote the projection of the footing on either

side of the wall by P, the reaction of the foundation-bed on this projecting portion P, per unit length of wall, will be PU. The CENTER OF ACTION of this force will be at a distance $\frac{1}{2} P$ from E or F and its moment at E or F will be

$$M = PU \times \tfrac{1}{2} P = \tfrac{1}{2} UP^2$$

or, since

$$P = \tfrac{1}{2} (l - w)$$

the value of M may be given in the form

$$M = \tfrac{1}{8} U (l - w)^2 \qquad (2)$$

The Error Involved in this second method is due to the assumption that the uplift on the projection P can be resisted by the extreme outer edge of the base of the wall. If the uplift on the projecting part is concentrated on the edge, then the edge must either compress or fail by crushing, which, in either case, would throw the center of support for the cantilever back from the edge of the wall; and this is contrary to the assumption used in calculating the moment. This method takes into consideration only the intensity of the reaction or uplift and the length of the projection, and is known as the PROJECTION-METHOD.

Comparison of Results. Comparing the results of the two methods, it will be seen that the load cannot act at the two edges E and F as assumed in Equation (2), nor ordinarily can it be uniformly distributed as assumed in Equation (1), but that the INTENSITY OF THE LOAD PER UNIT OF AREA will vary, being a MINIMUM at the center and a MAXIMUM near the edges of the base of the wall. The exact positions of the CENTERS OF ACTION are affected by various considerations which cannot be fully discussed in this chapter.

New Formula for Determining Bending Moments in Footings. The writer has devised a formula which gives values for the bending moment M half-way between the values given by Equations (1) and (2), and which closely corresponds to the assumption that, considering the forces on either side of the center of the wall, the CENTER OF ACTION of the half-load of the wall is at the center of the half-wall, when the projection equals zero, and, as the projection increases, moves toward a position which is two-thirds of the distance from the center of the wall to its edge. This formula may be expressed as follows:

$$M = \tfrac{1}{8} U (l - w) (l - \tfrac{1}{2} w) \qquad (3)$$

Or, substituting the value of U in terms of W,

$$M = \tfrac{1}{8} W (l - w) (1 - w/2l)$$

Weight and Pressure-Units. In practice W, the weight due to the wall, is generally given in pounds per linear foot of wall, and the allowable pressure on the foundation-bed, while frequently given in tons per square foot, should be reduced to pounds per square foot.

The Required Width of the Footing in feet is obtained by dividing the weight of the wall in pounds per linear foot of wall by the allowable unit load on the foundation-bed expressed in pounds per square foot.

Moment-Units. The moment tending to produce rupture may be calculated in foot-pounds or inch-pounds. If in Equations (1), (2) and (3) the dimensions l, w and P are in feet and U is in pounds per square foot, the resulting bending moment will be in foot-pounds per linear foot of wall. As the MOMENT OF RESISTANCE is generally stated in inch-pounds it is more convenient to have the MAXIMUM BENDING MOMENT or MOMENT OF RUPTURE * in inch-pounds. Thus, for Equation (1)

* In the flexure-formula the moment of resistance is made equal to the bending moment at any cross-section of the footing, and the maximum bending moment is sometimes called the moment of rupture.

$$M \text{ (in inch-pounds per foot of wall)} = 12\, M \text{ in foot-pounds,}$$

or
$$M \text{ (in inch-pounds)} = \tfrac{3}{2}\, U\, (l - w)\, l \qquad (1)'$$

Equation (2) in the same way becomes

$$M \text{ (in inch-pounds)} = \tfrac{3}{2}\, U\, (l - w)^2 \qquad (2)'$$

Or, using the more convenient form,

$$M = \tfrac{1}{2}\, UP^2$$

if we express the projection P in inches, instead of in feet, we will have

$$M \text{ (in inch-pounds per foot of wall)} = \tfrac{1}{24}\, UP^2$$

Similarly, Equation (3) becomes

$$M \text{ (in inch-pounds per foot of wall)} = \tfrac{3}{2}\, U\, (l - w)\, (l - \tfrac{1}{2} w). \qquad (3)'$$

Until Equations (3) or (3)′ are more generally accepted, an engineer or designer will avoid criticism and be perfectly safe in using Equation (1), and in the following pages the writer will use Equations (1) or (1)′ unless the contrary is stated.

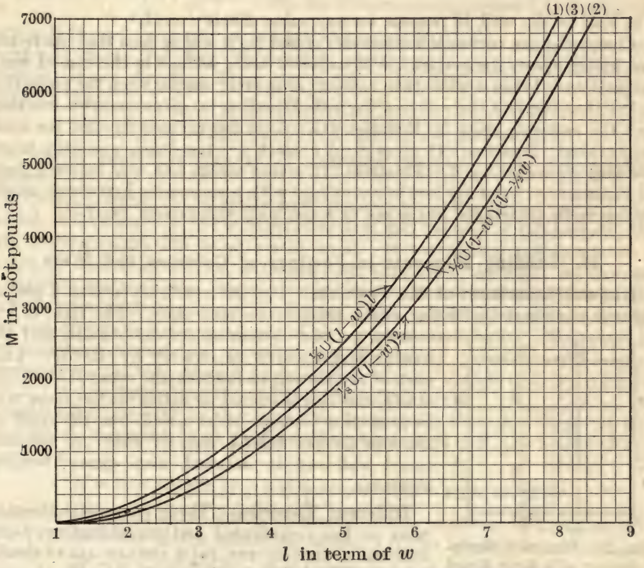

Fig. 24. Graphical Comparison of Bending Moments in Footings

Example. The following is an example illustrating the application of the foregoing formulas:

A 24-in wall transmits to the footing 42 000 lb per linear foot of wall. The allowable unit load on the foundation-bed is 3 600 lb per sq ft. What is the width and required MOMENT OF RESISTANCE * of the footing?

$$42\,000/3\,600 = 11\tfrac{2}{3} \text{ ft}$$

* In the flexure-formula the moment of resistance is made equal to the bending moment at any cross-section of the footing, and the maximum bending moment is sometimes called the moment of rupture.

Then, by Equation (1), we have

$$M = \tfrac{1}{8} \times 3\,600\,(11\tfrac{2}{3} - 2)\,11\tfrac{2}{3} = 50\,750 \text{ ft-lb}$$

If Equation (2) is used, we have

$$M = \tfrac{1}{8} \times 3\,600\,(11\tfrac{2}{3} - 2)^2 = 42\,050 \text{ ft-lb}$$

and by Equation (3)

$$M = \tfrac{1}{8} \times 3\,600\,(11\tfrac{2}{3} - 2)\,(11\tfrac{2}{3} - 1) = 46\,400 \text{ ft-lb}$$

Comparing the results we see that the moment by Equation (3) is the average of the moments by Equations (1) and (2).

Graphical Comparison of Bending Moments in Footings. Fig. 24 is a graphical comparison of the moments for varying ratios of l to w calculated by Equations (1), (2) and (3) on the assumption that

w = the width of wall = 1 ft;
U = the unit load on the foundation-bed = 1 000 lb per sq ft; and
$r = l/w$.

The load on the wall, in pounds, for any value of l, is 1 000 l.

Comparing the curves of Equations (1) and (2) it will be seen that the results are widely apart, the percentage of variation being highest in the case of small projections. When l is less than twice w, or in other words, when the projection is less than one-half the width of the wall, Equation (2) gives moments less than half the moments given by Equation (1). Equation (2) may be used for small projections. Equation (1) gives results which are too large, especially where the projections are small. Equation (3), giving results half-way between those of Equations (1) and (2) and in accordance with a reasonable hypothesis, would appear to be preferable, but is not in accordance with present practice.

21. Bending Moments in Footings of Columns and Piers

General Statement of the Problem. Fig. 25 represents in plan a pier or column resting on a footing which projects on four sides. The base of the column or pier is represented by *ABCD*, and the footing and its area of support by *EFGH*. That part of the footing included in the areas *MNOP* and *QRST* can be considered as acting in the same way as projecting footings under a wall, but the uplift on the four corners *EQMA*, etc., on which no superimposed wall-load is imposed, also causes bending moments.

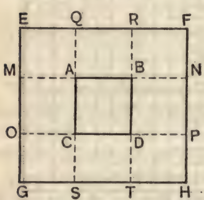

Fig. 25. Plan of Column-footing with Four Equal Projections

Different Theories. There are several theories, more or less complicated and unsatisfactory, as to how the UPLIFT ON THE FOUR CORNER-AREAS should be determined. The discussion of these theories would be out of place in this chapter. In a square footing, the projection is not over one-half the width of the superimposed base, the four corner-areas will not aggregate over 25% of the total area of the footing, and it may then be assumed that the bending moment is the same as if the base of the column or pier extended like a wall across the entire footing, as is shown in Fig. 26. To insure these conditions, when the projection of the footing exceeds ½ w, and in all cases when the footing is not homogeneous, as when a grillage of steel is used, the load of the column must be distributed over the width of the footing by a GIRDER OR BOLSTER or by an extension of the column-base. In case the footing is in several layers, each

layer must extend the full width of the underlying layer. With such construction it is evident that the bending moment will be the same as if the GIRDER or BOLSTER were a wall and Equation (1) will be applicable.

Bending Moments in Column-Footings. For column-footings Equation (1) can be used, taking the total load in place of the load per foot, and the result will then be the total bending moment.

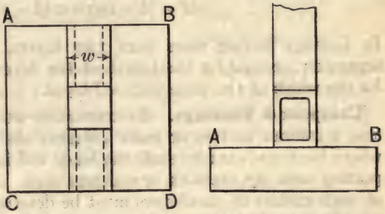

Fig. 26. Column-footing Treated Like Wall-footing

Example. A column carrying 96 tons is to be supported on a square concrete slab. The cast-iron column-base is 2 ft square. The allowable pressure on the foundation-bed is 6 tons per sq ft. What is the MAXIMUM BENDING MOMENT in the slab?

The area of support = 96/6 = 16 sq ft = 4 by 4 ft. The projection is ½ (4 – 2) = 1 ft, or one-half the width of the base, and by the foregoing rule we can calculate the bending moment as if the base of the column extended in one direction across the footing. Applying a convenient form of Equation (1)

$$M = \tfrac{1}{8} \times 192\,000 \text{ lb } (4 - 2) = 48\,000 \text{ ft-lb, or } 576\,000 \text{ in-lb}$$

The footing must therefore be of sufficient depth to resist this bending moment.

If in this example the allowable unit pressure on the foundation-bed is 2 tons instead of 6 tons per sq ft the supporting area and the area of the bottom concrete footing course will be 96/2 = 48 sq ft. If the footing course can be a square its dimensions will be, with sufficient exactness, 7 by 7 ft. By the rule given, since the projection exceeds one-half the width of the base, there should be a BOLSTER extending across the footing. The bolster will be, therefore, 7 ft long and may properly be composed of two or more steel beams. The cast-iron base may be dispensed with, in which case the base of the column will be provided with a steel base or with flange-angles. Let us assume that the column-base is 1 ft 6 in square and the width of the bolster 2 ft.

The bending moment in the bolster is determined, then, by Equation (1), using 1½ ft, the width of the column-base, for w, and 7 ft, the length of the bolster, for l.

$$M = \tfrac{1}{8} \times 192\,000 \,(7 - 1\tfrac{1}{2}) = 132\,000 \text{ ft-lb} = 1\,584\,000 \text{ in-lb}$$

The bending moment in the slab is determined in the same way by Equation (1), using 2 ft, the width of the bolster, for w, and 7 ft, the length of the slab, for l.

$$M = \tfrac{1}{8} \times 192\,000 \,(7 - 2) = 120\,000 \text{ ft-lb} = 1\,440\,000 \text{ in-lb.}$$

Footings Other Than Square in Plan. In case it is necessary to use some other shape than a square for the supporting area the resulting moments in the slab and bolster will vary from those calculated above. If in the foregoing example the supporting area, for any reason, is necessarily made 6 by 8 ft, giving 48 sq ft as the required area, and if the bolster is parallel with the 6-ft side, the moment in the bolster will be

$$M = \tfrac{1}{8} \times 192\,000 \,(6 - 1\tfrac{1}{2}) = 108\,000 \text{ ft-lb} = 1\,296\,000 \text{ in-lb}$$

and the moment in the slab will be

$$M = \tfrac{1}{8} \times 192\,000 \,(8 - 2) = 144\,000 \text{ ft-lb} = 1\,728\,000 \text{ in-lb}$$

or, the moment in the bolster is less and the moment in the slab is greater than in the case of the 7 by 7-ft supporting area. If the bolster runs parallel with the long side, the moments will be, for the bolster,

$$M = \tfrac{1}{8} \times 192\,000\,(8 - 1\tfrac{1}{2}) = 156\,000 \text{ ft-lb}$$

and for the slab,

$$M = \tfrac{1}{8} \times 192\,000\,(6 - 2) = 96\,000 \text{ ft-lb}$$

In footings having more than two layers, each layer must be investigated separately, using l for the length of the layer which is being determined and w for the width of the superimposed layer.

Compound Footings. In COMPOUND FOOTINGS where, for example, a wall and a column or two or more columns are supported by a single footing, or where loads are cantilevered, the loads will in general be distributed to the supporting area by GIRDERS or CANTILEVERS. The shears and bending moments of such girders or cantilevers must be determined for each case by the methods used in the calculations of beams and girders in Chapters XV and XX.

22. Design of the Footings

Materials used for Footings. To possess the required strength the SAFE MOMENT OF RESISTANCE of the footing must be at least equal to the MOMENT OF RUPTURE, calculated as explained in the preceding paragraphs. Masonry, whether of brickwork or stone, is not generally suitable for any but the lightest buildings, as its tensional strength is low. Concrete, plain or reinforced, or grillages of steel embedded in concrete, are generally employed. (See Chapter III for footings for light buildings.)

Footings of Homogeneous Slabs. If the footing is composed of a SLAB OF HOMOGENEOUS MATERIAL, as a block of granite or other reliable building stone, or a single layer of concrete, the MOMENT OF RESISTANCE is, by the well-known flexure-formula for rectangular cross-sections, $M_r = \tfrac{1}{6}\, bd^2 S$ (see Chapters X, XV and XVI) in which

d = the depth or thickness of the footing, in inches;
b = the breadth of the footing, in inches;
S = the allowable unit tensile stress of the material, in pounds per square inch;
M_r = the moment of resistance.

Placing M, the moment of the forces tending to cause rupture, equal to M_r, for a length of wall equal to 1 foot we have

$$b = 12 \text{ in}$$

and

$$d^2 = \tfrac{1}{2}\, M/S \qquad (4)$$

Substituting in Equation (4) the value for M in inch-pounds as determined by formulas (1), (2) and (3) and a value for S as given in the following paragraph, the required depth d can be determined.

Safe Tensional Strength for Materials in Footings. The values of S, the ALLOWABLE UNIT TENSILE STRESS, for concrete or stone must include a high FACTOR OF SAFETY, as experiments show wide variations in the tensional strength and in the MODULUS OF RUPTURE OF FLEXURAL STRENGTH of such materials. The following values for S in pounds per square inch include a factor of safety of from 8 to 10 and should not be exceeded. (See, also, Table III, page 628, Chapter XVI.)

	S in lbs per sq in
For brickwork or masonry in lime mortar........	from 0 to 10
For brickwork or masonry in cement mortar.......	from 10 to 40
For concrete, 1 : 3 : 6.........................	from 15 to 25
For concrete, 1 : 2½ : 5........................	from 20 to 40
For concrete, 1 : 2 : 4.........................	from 30 to 50
For sandstone or limestone in monolithic blocks....	from 75 to 150
For granite in monolithic blocks................	from 100 to 250

Example of Concrete-Footing Design. Concrete Cast as a Unit. A concrete footing course 4 ft wide supports a wall 2 ft thick. The load on the foundation bed is 28 000 lb per lin ft of wall, or 7 000 lb per sq ft. Assuming a value for S of 35 lb per sq in, what is the required depth for the concrete footing course?

The moment of rupture from one form of Equation (1) is

$$M = \tfrac{3}{2}\, W\,(l - w), \quad \text{or} \quad \tfrac{3}{2} \times 28\,000\,(4 - 2) = 84\,000 \text{ in-lb}$$

Substituting in Equation (4)

$$d^2 = \tfrac{1}{2} \times 84\,000/35 = 1\,200, \quad \text{or} \quad d = 35 \text{ in}$$

By Equation (2)′ the moment of rupture is

$$M = \tfrac{1}{24}\, UP^2 = \tfrac{1}{24} \times 7\,000 \times 12 \times 12 = 42\,000 \text{ in-lb}$$

and

$$d^2 = \tfrac{1}{2} \times 42\,000/35 = 600, \quad \text{or} \quad d = 24 \text{ in} +$$

The depth determined by Equations (1) or (1)′, as previously noted, errs on the side of safety. The result by Equations (2) or (2)′ conforms more nearly with usual practice, and as the projection is small compared with the width of the wall, it may be used, or an intermediate value, as determined by Equations (3) or (3)′, may be considered amply safe.

Stepped Footings. If the concrete footing is cast in one uninterrupted operation so as to act as a SINGLE GIRDER for its entire depth, a considerable saving of material may be effected by forming steps, as shown in Fig. 27. If the steps are of equal height the total projection should be equally divided between the steps. If the footing is cast in several layers, or if a granite slab is superimposed on a bed of concrete, then each layer must be figured separately and the width of the superimposed layer used in place of w, the width of the wall.

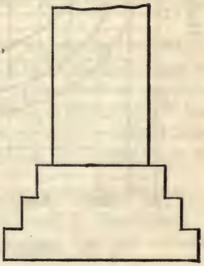

Fig. 27. Concrete Stepped Wall-footing

Caution in Design of Footings of Several Layers. Equation (2) should not be used where the footing consists of several layers, as the error due to the erroneous assumption is cumulative and would result in a serious concentration on the outer edges of the upper layers.

Example of Footings of Several Layers. In the case of footings cast in separate layers the calculations should be made as follows: Let l_1 = the length of the footing having a moment, M. From Equation (1), reduced to inch-pounds,

$$l_1 = \frac{2\,M}{3\,W} + w$$

Having decided on the depth of each layer, say 15 in, and a value of S, say 35 lb, for concrete, then, from the flexure-formula, $M = M_r = \tfrac{1}{6} \times 12 \times 15^2$

$\times$ 35 = 15 750 in-lb, which, substituted in the above equation, will give the value of l_1, or the length of the top course. Having determined l_1, the length of the second course, l_2, is found in the same way, using l_1 for w, and so on until the required width of the footing is reached. The dimensions l and w are to be taken in feet.

Comparison of Unit and Separate-Layer Footings. Footings made in separate layers are very uneconomical in the amount of material required, when compared with those cast in one operation. If the footing in the previous example is designed on the separate-layer basis and the courses assumed to be 15 in thick, their lengths are as follows:

$$l_1 = \frac{2\,M}{3\,W} + w = [(2 \times 15\,750)/(3 \times 28\,000)] + 2 = 2.375 \text{ ft}$$

Also

$$l_2 = 2.75 \text{ ft}, \quad l_3 = 3.125 \text{ ft}, \quad l_4 = 3.50 \text{ ft} \quad \text{and} \quad l_5 = 3.875 \text{ ft}$$

As l_5 is nearly 4 ft, the required length, it may be made so by increasing the thickness of the bottom course to 16 in. The total thickness of the footing is therefore (4 $\times$ 15 in) + 16 in = 76 in instead of 35 in, as previously determined by Equation (1) for the footing cast as a unit.

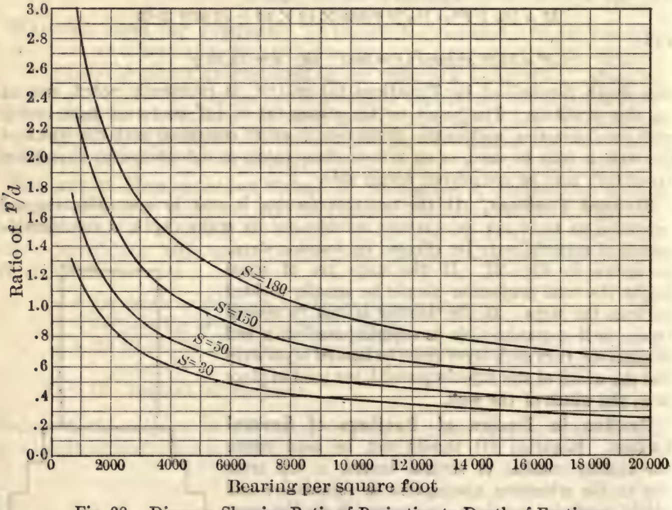

Fig. 28. Diagram Showing Ratio of Projection to Depth of Footings

Rule-of-Thumb Methods for Projections and Steps in Footings. Various ARBITRARY RULES are in use which purport to give for different materials of construction so-called SAFE PROJECTIONS for given depths of footing or to give the SAFE RATIO between the projection and the depth of a footing. These rules ignore the fact that the uplift varies and they are entirely unreliable, although such RULES-OF-THUMB are often incorporated in the building codes of cities. (See Chapter III, page 224.)

Example. The safe projection for offsets in brickwork is frequently given in building codes and in text-books as 3 in for a double course of bricks or for

a depth of about 5 inches, the corresponding ratio being 0.6. If we assume the value of S for brickwork at 20 lb per sq in, this offset will be safe when the uplift is less than 2 666 lb per sq ft, but not safe when the uplift is over 2 666 lb per sq ft.

Ratio of Projection to Depth of Footing. For footings of homogeneous material, however, having a small projection and where Formula (2) can be used safely, it is possible to calculate a so-called SAFE RATIO OF PROJECTION for a given unit load. From Equation (2)′ and Equation (4), derived from the formula for the MOMENT OF RESISTANCE for beams of homogeneous material and rectangular cross-section, the following formula may be derived:

$$p/d = \sqrt{48\,S/U} \qquad (5)$$

in which all dimensions are in inches, S in pounds per square inch, and U in pounds per square foot. The quantity p/d is the ratio of the projection to the depth of the beam or footing. For a given value of S the ratio will vary inversely as the square root of U.

The diagram (Fig. 28) shows curves for different values of S and U from which the ratio of projection to depth of footing may be taken. Thus, for a concrete footing for which the allowable unit stress, S, in tension is, say 30 lb per sq in, if the load, U, on the foundation-bed is 3 000 lb per sq ft, the allowable projection will be 0.69 times the depth of the footing course. If the concrete is 12 in thick, the allowable offset will be 8.3 in. Conversely, for a given offset, say 12 in, when the unit load is 3 000 lb and S = 30 lb as before, the required depth will be 1.45 times the offset.

23. Steel Grillages in Foundations*

Advantages in the Use of Steel-Beam Grillages. When it is desirable to avoid the deep excavation required for concrete or masonry footings, and when the load of a wall has to be distributed over a wide area of support, STEEL RAILS or STEEL BEAMS are frequently advantageously used to give the required moment of resistance with a minimum of depth. Steel beams are generally cheaper and preferable to rails, although second-hand rails have frequently been used as an expedient.

Preparing the Bed and Setting the Beams. The foundation-bed should be first covered with a layer of concrete not less than 6 in in thickness and so mixed and compacted as to be as nearly impervious to moisture as possible. The beams should be placed on this layer, the upper surfaces brought to a line and the lower flanges carefully grouted so as to secure an even bearing. Subsequently, concrete should be placed between and around the beams so as to permanently protect them.

Requirements for Steel Grillages. In determining the number and size of the beams for any given footing the following points should be considered:

(1) The beams must resist the MAXIMUM BENDING MOMENT, and this without undue DEFLECTION.

(2) The beams must resist the SHEARING-STRESSES, the meeting of which requirement ordinarily provides against CRUSHING.

(3) The beams must not be spaced so far apart that there is danger of the concrete filling between the beams failing to DISTRIBUTE THE LOAD.

(4) The beams must not be spaced so near together as to prevent the placing of concrete between them. The clear space between the flanges of the top layer should preferably be not less than 2 in and should be somewhat more for the lower layers.

* See pages 678 to 680 for an example of a continuous girder in grillage foundation.

(5) Where the BENDING MOMENT is the governing feature, of two beams of equal weight, the deeper beam should be used. Thus, if the required SECTION-MODULUS is 147, a 20-in 80-lb beam might be used; but a 24-in 80-lb beam is stiffer and stronger in bending.

(6) Where the SHEAR is the governing feature, of two beams of equal weights, the smaller beam is the stronger. Thus, the SHEARING VALUE of a 20-in 80-lb beam is greater than that of a 24-in 80-lb beam and is nearly equivalent to that of a 24-in 90-lb beam. However, on account of the greater STIFFNESS of the deeper beam it is sometimes advisable to use it even though the cost is increased.

Spacing of Beams in Grillage. Table IX gives the LIMITING SPACING for steel beams, based upon the safe capacity of the concrete filling acting as a beam, for loads of from 1 to 6 tons per sq ft. Since, however, in such small spans there is considerable ARCHING EFFECT, the concrete will safely distribute the load on larger spans than those given in the table, provided a sufficient number of tie-rods of proper size are used to take up the THRUST of the arches.

Table IX. The Limiting Spacing for Steel Beams Used With Concrete Filling

Depths of beams	Spacing of beams for the following pressures per square foot											
	1 ton		2 tons		3 tons		4 tons		5 tons		6 tons	
in	ft	in	ft	in	ft	in	ft	in	ft	in	ft	in
6	1	3	0	11	0	10	0	9	0	8	0	7
7	1	6	1	1	0	11	0	10	0	9	0	8
8	1	8	1	3	1	1	0	11	0	10	0	9
9	1	11	1	5	1	2	1	0	0	11	0	10
10	2	1	1	6	1	4	1	2	1	1	1	0
12	2	5	1	10	1	6	1	4	1	3	1	2
15	3	0	2	3	1	10	1	8	1	6	1	5
18	3	8	2	8	2	3	1	11	1	9	1	8
20	4	0	2	11	2	5	2	2	1	11	1	10
24	4	9	3	6	2	11	2	7	2	4	2	2

The Design of a Wall-Footing of steel beams is illustrated by the following example: A 24-in wall carries 42 000 lb per lin ft. What should be the size and spacing of steel beams to distribute the load over the foundation-bed at 3 600 lb per sq ft? The required width of the footing is 42 000/3 600 = 11 ft 8 in and the bending moment by Equation (3) is 556 800 in-lb per lin ft of wall. The amount of shear, by the formula given on page 170, is $S = W\ (l - w)/l$, or 34 800 lb. As the beams are in double shear the single shear per linear foot of wall is 17 400 lb. The required section-modulus per linear foot of wall is obtained by dividing the bending moment by the allowed fiber-stress in the steel, or 556 800/16 000 (assumed fiber-stress) = 34.8. By referring to Table IV, page 355, giving the section-moduli of steel beams we find that a 12-in 31½-lb beam has a section-modulus of 36. To satisfy the condition of bending, the beams must not be spaced more than 36/34.8 = 1.03 ft, center to center. To satisfy the condition of web-crippling due to direct compression, the unit compressive stress must not exceed the value of S_b, Table II, page 575, which, for a 12-in 31½-lb beam, is 13 060 lb per sq in. The area of the beam resisting compression is the length over which the load is distributed, times the web-thickness. Some authorities consider that the load is distributed over a length

equal to the loaded portion of the beam plus one-half the depth of the beam, but in this and the following example the length of only the loaded portion is taken. In this case the area is therefore $24 \times 0.35 = 8.4$ sq in. If the beams are spaced 1.03 ft on centers the unit direct compression is $42\,000 \times 1.03/8.4 = 5\,150$ lb, which is well within the allowed stress given by Table II, page 575. To satisfy the condition of web-crippling due to shear, the shearing-stress must not exceed the value as derived from the formula for allowable shear. (See, in Chapter XV, paragraphs and foot-notes relating to Buckling of Beam-Webs and to the illustrative Example 15 in that chapter.) The approximate, allowed, unit shearing value may be obtained by dividing the value of S_b (Table II, page 575) by the factor F, the values of which are given in Table IXa, following. For example, for a 12-in 31½-lb beam this shearing value $= 13\,060/1.65 = 7\,915$ lb per sq in. The shearing capacity of the beam is obtained by multiplying this unit stress by the depth of beam times the web-thickness, or $7\,915 \times 12 \times 0.35 = 33\,240$ lb, or much more than required. Only one of the conditions of web-crippling need be considered by applying the following rule: If the shear divided by the depth of the beam is greater than the total load divided by the product of the distance (over which the load is distributed) by the factor F, investigate for shear; if otherwise, investigate for direct compression. This rule may also be expressed as follows: According as $(l - w)/l$ is greater or less than $2\,D/w'F$, investigate for shear or for compression. Here l = length of beam, w = loaded portion of beam, D = depth of beam, w' = length of beam over which the load is assumed to be distributed (often taken $= w + \frac{1}{2} D$) and F = the factor for the given beam obtained from Table IXa. All dimensions must be taken in the same unit. If, instead of the 12-in beams, 15-in 42-lb beams, having a section-modulus of 58.9 are used, the spacing will be $58.9/34.8 = 1.7$ ft nearly, say 1 ft 8 in. By referring to Table IX, page 182, it is seen that the spacing of the beams is well within the safe limit of the concrete and no tie-rods are necessary.

Table IXa. Values of Factor F* for Shearing Values for Various Beams

Beams	For standard-weight beams	For heavy-weight beams
12-in beam	1.65	1.52
15-in beam	1.71	1.50
18-in beam	1.76	1.58
20-in beam	1.77	1.62
24-in beam	1.91	1.67

* The factors, F, which have been deduced to be used in connection with S_b, Table II, pages 574–5, to give the safe unit shearing value based on web-crippling, will help greatly in investigations of shears in case tables of safe shears are not obtainable. It is to be noted, however, that the values derived from the use of F are approximate only, as this factor is a little different for every beam; and to give its value for every beam would require as much space as complete tables of safe shears. The values of F are not given for the new sections of light beams as they are not usually good sections for grillages. It may be mentioned that the standard weight for each size of beam for which F is given is always the next weight higher than the minimum weight given in Table II, pages 574–5, except for the 20-in beams, for which the minimum weight, 65 lb, is also the standard weight. The rule given above for determining whether web-crippling based on shear or on direct compression is the determining condition eliminates one of the calculations to be made in investigating grillages.

The Design of a Column-Footing of steel beams is illustrated by the following example: A column carries 576 tons. The allowable pressure on the foundation-bed is 3 tons per sq ft. What should be the arrangement, number and size of the steel beams composing the grillage? The required area of support = 576/3 = 192 sq ft. In order to make the problem as general as possible let it be supposed that practical considerations limit the width of the footing to 12 ft. The dimensions of the concrete mat on which the lower layer of beams rests will be 12 by 16 ft. By referring to the diagram (Fig. 28) we find that if the mat is made 12 in thick an offset of 6 in is permissible. The dimensions of the lower layer of beams will therefore be 11 by 15 ft. A suitable grillage for the given conditions may be designed of two or of three layers. If two layers are used the length of the top beams will be 11 ft. Assuming the column-base = 30 in, the loaded portion = 2½ ft, and by Formula (1), the bending moment * = ¼ × 1 152 000 lb × (11 − 2½) × 12 × ½ = 14 688 000 in-lb, from which the required section-modulus (at 16 000-lb maximum fiber-stress) = 918. By referring to Table IV, Chapter X, five 24-in 90-lb beams have a section-modulus of 932.5 and consequently satisfy the condition of bending. By applying the rule given in the preceding paragraph for the design of a wall-footing, to see if web-crippling due to shear or to compression is to be investigated, $(l - w)/l =$ 0.773 and $2\,D/w'F = 0.958$, which, being greater than 0.773, shows that the beams should be investigated for web-crippling due to compression, by the method explained in the previous example. It will be found that the five 24-in 90-lb beams also satisfy this condition and will therefore be used. Their flange-width is about 7⅛ in, so they should be spaced about 9½ in on centers, requiring the length of the column-base to be about 3 ft 9 in. The calculation for the lower layer is similar, the length of the beams being 15 ft and the loaded portion, 3 ft 9 in. It is rarely necessary to investigate the lower layer for web-crippling, the condition of bending, except for the top layer, being usually the governing feature. If, owing to conditions of bending, it is not practicable to make the beams of the top layer sufficiently long to extend across the required width of the concrete mat, it is then necessary to make the grillage of three layers. The calculation for a three-layer grillage for the same problem as the preceding is as follows:

Calculation of the Top Layer. For web-crippling due to compression, 1 152 000 lb = $S_b \times w' \times t \times n$, where S_b = the allowable unit stress, w' = the length of beam over which the load is assumed to be distributed, t = the web-thickness and n = the number of beams. Referring to Table II, Chapter XV, and assuming a 20-in 75-lb beam to be used, S_b = 13 660 lb per sq in and t = 0.649 in. Taking w' = 30 in (the width of the column-base), 13 660 × 30 × 0.649 = 265 960 lb and the value for five beams is 1 329 800 lb, which is more than enough. But it is found that five 20-in 70-lb beams would not be sufficient. It will be economical to make these beams of the greatest length for which they will resist bending. The section-modulus of one beam is 126.9; and the total M_r = 5 × 126.9 × 16 000 (assumed fiber-stress). This may be determined, also, by Formula (1) in which $M = ¼\,WP$. From these equations the projection P = 35¼ in, and the length of the beams is therefore (2 × 35¼) + 30 (the width of the base) = 100½ in, or approximately 8 ft 4 in. By applying the foregoing rule to see if web-crippling due to shear must be considered, (100 − 30)/100 = 0.7 which is less than 40/(30 × 1.62) = 0.82, and the shear need not be investigated.

* It is to be noted that the bending moment is the same as for a beam uniformly loaded with 576 tons on a span of 8½ ft, $(l - w)$, and that the number and size of the required beams may be taken from the tables giving the safe loads of beams. See Table IV, Chapter XV.

The width of the flanges of these beams is nearly 6½ in, so that they should be spaced from 8½ to 9 in, thus making the required length of column-base about 3 ft 6 in.

Calculation of the Second Layer. Since the length of the top layer is limited to 8 ft 4 in and the width of the lowest layer is 11 ft, it will be necessary to have an intermediate layer. This will cover the area given by the length of beams of the top layer and the width of the lower layer, or 8 ft 4 in by 11 ft. The beams will of course be at right-angles to those of the top layer, so their length will be 11 ft, and they are to be so spaced as not to exceed 8 ft 4 in. Since the width of the top course is 3½ ft, their projection is (11 ft − 3½ ft)/2 = 3¾ ft, the amount of single shear is 1 152 000 × 3.75/11 = 392 720 lb and the bending moment is ¼ × 1 152 000 × 45 in = 12 960 000 in-lb. Using 16 000 lb as the fiber-stress the required section-modulus is 810. By referring to Table IV, Chapter X, for section-moduli and determining the maximum shear as above explained, we find that ten 15-in 60-lb beams will have a total section-modulus of 812, and they will also be ample for shear. Furthermore, ten beams spaced to cover a width of 8 ft 4 in will give a spacing, center to center of beams, of about 10 in, which is sufficient. It would be better, however, to use ten 18-in 55-lb beams.

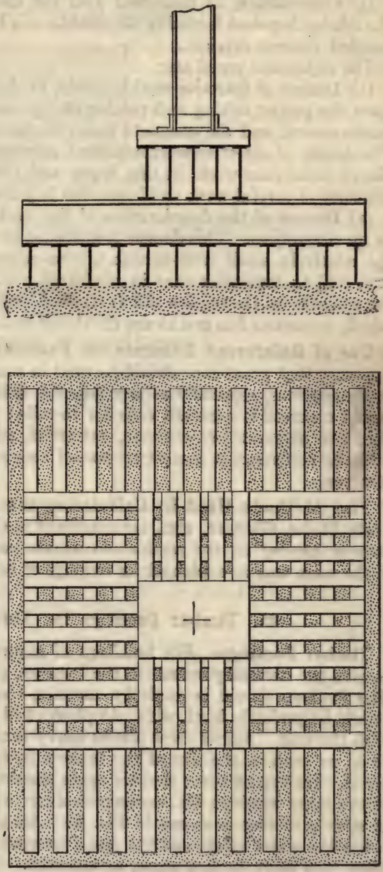

Fig. 29. Steel-beam Grillage Column-footing

Calculation of the Bottom Layer. Taking the effective width of the middle layer as 8 ft, the projection of the beams is (15 ft − 8 ft)/2 = 3½ ft. Then similarly to the above, the shear = 268 800 lb. M = 12 096 000 in-lb, from which the section-modulus = 756, and thirteen 15-in 42-lb beams, spaced 10½ in on centers, will be required, or two 15-in 60-lb beams and ten 15-in 42-lb beams may be used, increasing the spacing between the beams. In this case the heavy beams should be placed nearest to the center of the footing. This grillage is illustrated in Fig. 29.

24. Reinforced-Concrete Footings

Advantages and Disadvantages. Reinforced concrete has in recent years been largely used for footings. The arguments in favor of its use are:

(1) Low cost of the footing-construction;

(2) Reduction in the amount of excavation required;

(3) Convenience, as compared with the use of steel-beam grillages, in that the reinforcing-steel is readily obtainable, can be cut to length on the work and handled without derricks.

The objections urged are:

(1) Danger of defective workmanship, as the strength of the footing depends upon the proper mixing and placing of the concrete, the proper placing of the reinforcement and the complete union of the concrete with the reinforcement. The danger of defective workmanship is increased by reason of the usual difficulties of foundation-work, in that water and mud are generally present and the difficulty of careful work and inspection is greater.

(2) Danger of the deterioration of the steel reinforcement either by rusting or by electrolysis. This danger is increased by the presence of moisture and by the relatively small cross-section of the reinforcing-bars. In this connection it is well to remember that in reinforced-concrete girders as usually designed the concrete on the tension side is stressed beyond its elastic limit, as a result of which, numerous fine cracks are developed under the figured load.

Use of Reinforced Concrete for Foundations. From the foregoing it is apparent that great care should be used in connection with reinforced concrete in foundations, especially as any defect is difficult to detect or repair. Reinforced concrete is used not only for so-called MATS or SLABS but is frequently used for DISTRIBUTING-GIRDERS, BOLSTERS and even for CANTILEVERS. The author's preference is against reinforced concrete for foundations for important structures.

The Methods Used in Calculating the Strength of Reinforced-Concrete Slabs, Girders, etc., are explained in Chapters XXIV and XXV. The stresses coming on the reinforced-concrete construction are to be determined in the same way as explained for footings of other materials.

25. Timber Footings for Temporary Buildings

Timber Footings. For buildings of moderate height timber may be used to give the necessary spread to the footings, provided water is always present. The footings should be built by covering the bottom of the trenches, which should be perfectly level, with 2-in planks laid close together and longitudinally with the wall. Across these planks heavy timbers should be laid, spaced about 12 in on centers, the size of the timbers being proportioned to the transverse stress. On top of these timbers again should be spiked a floor of 3-in planks of the same width as the masonry footings which are laid upon it. A section of such a footing is shown in Fig. 30. All of the timber-work must be kept below low-water mark, and the space between the transverse timbers should be filled with sand, broken stone, or concrete. The best woods for such foundations are oak, long-leaf yellow pine and Norway pine. Many of the old buildings in Chicago rest on timber footings.

Calculations for the Sizes of the Cross-Timbers. The sizes of the transverse timbers should be computed by the following formula:

$$\text{Breadth in inches} = \frac{2 \times w \times p^2 \times s}{d^2 \times A},$$

w representing the bearing resistance of the foundation-bed in pounds per square foot, p the projection of the transverse timbers beyond the 3-in planks, in feet, s the distance on centers of the timbers in feet, and d the assumed depth of the beam in inches. A is the constant for strength. The values recommended for it are 67 for long-leaf yellow pine and white oak, 44 for Norway pine, and 39 for common white pine or spruce. (See Table II, page 628.)

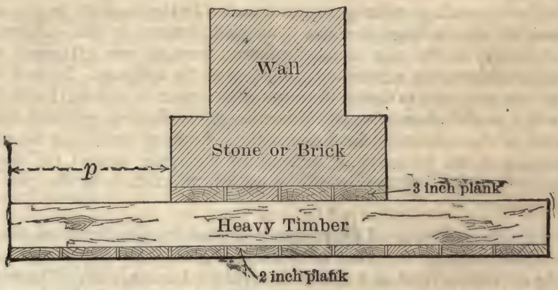

Fig. 30. Spread Footing of Timber

Example. The side walls of a given building impose on the foundation a pressure of 20 000 lb per lin ft; the soil will only support, without excessive settlement, 2 000 lb per sq ft. It is decided for economy to build the footings as shown in Fig. 30, using long-leaf yellow-pine timber. What should be the size of the transverse timbers?

Solution. Dividing the total pressure per linear foot by 2 000 lb, we have 10 ft for the width of the footings. The masonry footing we will make of granite or other hard stone, 4 ft wide, and solidly bedded on the planks in Portland, cement mortar. The projection p of the transverse beams will then be 3 ft. We will space the beams 12 in on centers, so that $s = 1$, and will assume 10 in for the depth of the beams. Then, by the formula,

$$\text{the breadth in inches} = \frac{2 \times 2\,000 \times 9 \times 1}{100 \times 67} = 5.37 \text{ in}$$

and we should use 6 by 10-in timbers, spaced 12 in on centers. If spruce timber were used we should substitute 39 for 67, and the result would be a little over 9 in.

Foundations for Temporary Buildings. When temporary buildings are to be built on a compressible soil, the foundations may, in some parts of the country, be constructed more cheaply of timber than of any other material, and in such cases the durability of the timber need not be considered, as when it is sound it will last two or three years in almost any place, if thorough ventilation is provided. The World's Fair buildings at Chicago (1893) were, as a rule, supported on timber platforms, proportioned so that the maximum load on the soil would not exceed 1¼ tons per sq ft. Only in a few places over MUD-HOLES were pile foundations used.*

* A description of the foundations of these buildings may be found on page 70 of Building Construction and Superintendence, Part I, Masons' Work, by F. E. Kidder. The values given there to the term A of the formula are larger than those used in this edition of the Pocket-Book and are still allowed by some building codes.

26. General Conditions Affecting Foundations and Footings

General Considerations. Where the footings of a building rest on wet sand, or on clay, it is important that any movement of the material forming the foundation-bed be prevented if possible. In many cases it is advisable to connect all footings with a concrete floor to prevent any UPLIFT of the foundation-bed between the footings. Where unequal settlement is apprehended it is inadvisable to have long columns firmly attached to the footings, as any unequal settlement of the footings develops a BENDING-STRESS in the column; such bending-stresses, in the case of long columns, may become extremely serious, resulting possibly in the rupture or distortion of the columns. In such cases it has even been proposed to design the bases of the columns with BALL-AND-SOCKET joints which would allow unequal settlement of the footings without distortion or bending of the columns. Such connections, however, could not be generally used because of the necessity of bracing the structure against the horizontal pressure of the wind, but they would be entirely practicable in the case of long interior columns.

The Minimum Depth of Footings is limited by the depth of the cellar, by the requirements of the cellar as to whether part of the footings can project above the cellar-floor level, and by the depth of the footing itself. The minimum depth will be advantageously exceeded if, by a slight increase in depth, a material capable of sustaining a higher unit load is found on which to rest the footings; or if, as explained in previous articles of this chapter, greater security is afforded by locating the footing at a greater depth. These considerations will influence the design of a footing and in all cases should be taken into consideration. In some cases it may be cheaper to abandon the use of a SPREAD FOOTING of any type and resort to PILES OR MASONRY CONSTRUCTION going to ROCK or to some other solid substratum. Where there is any question on this point, careful comparison should be made of the advantages and costs of the two methods. In general, however, it will be cheaper to spread footings immediately below the cellar-excavation level than to employ any of the various deep-foundation methods.

Deep Foundations are necessary when the material at the level at which SPREAD FOOTINGS would ordinarily be constructed is not suitable, or in case it is desirable for any reason to carry the foundations of the building down to an underlying stratum of greater supporting power. Recourse must then be had to one or more of the following expedients:

(1) Wooden piles;
(2) Concrete piles;
(3) Piers or walls constructed in pits or trenches, or by other methods, and going down to the required depth to reach a solid stratum.

27. Wooden-Pile Foundations

The Use of Wooden Piles. When it is required to build upon a compressible soil that is constantly saturated with water and of considerable depth, the most practicable method of obtaining a solid and enduring foundation for buildings of moderate height is by driving wooden piles. Many buildings in the city of Boston, Mass., and several tall office-buildings of New York City and Chicago, rest on wooden piles, and they are extensively used for supporting buildings, grain-elevators, etc., erected along the water-front of coast and lake cities. The durability of wooden piles in ground constantly saturated with water is beyond question, as they have been found in a perfectly sound condition after the lapse of from six to seventeen centuries.

Municipal Requirements. The laws of Boston require that wooden piles shall be capped with block-granite levelers or with Portland-cement concrete, and that the spacing shall not exceed 3 ft between centers. The laws of Chicago require that wooden piles shall be driven to rock or hard-pan and capped with grillage of timber, concrete, or steel, or a combination of these. The laws of New York specify a minimum diameter of 5 inches and a maximum spacing of 3 feet between centers.

The Maximum Loads Allowed on Wooden Piles in various cities are as follows: Atlanta, 20 tons; Philadelphia, 20 tons; Buffalo, 25 tons; Minneapolis, 20 tons; Richmond, 25 tons; St. Louis, as many tons as the piles will safely support; Chicago, 25 tons; Louisville, 20 tons; St. Paul, 25 tons; New York, 20 tons; Portland, Ore., 25 tons; Cleveland, 25 tons. Most of the above cities also limit the allowed load by Wellington's formula which is hereinafter given on page 193, under the heading, Bearing-Power of Piles.

Kinds of Wood Used for Piles. Wooden piles are made from the trunks of trees and should be as straight as possible and not less than 5 in in diameter at the small end for light buildings, or 8 in for heavy buildings. The woods generally used for piles are spruce, hemlock, white pine, Norway pine, long-leaf and short-leaf yellow pine, pitch-pine, cypress, Douglas fir, and occasionally oak, hickory, elm, black gum and basswood. There does not appear to be much difference in the woods as to durability under water, but the tougher and stronger woods are to be preferred, especially where the piles are to be driven to hard-pan and heavily loaded.

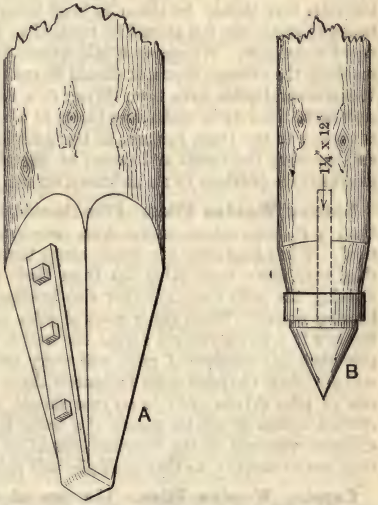

Fig. 31. Points of Wooden Piles Prepared for Driving

Preparing Wooden Piles for Driving. The piles should be PREPARED FOR DRIVING by cutting off all limbs close to the trunk and sawing the ends square. It is probably better to remove the bark, although piles are more often driven with the bark on, and it is doubtful if the bark makes much difference one way or the other. For driving in soft and silty soils, experience has shown that the piles drive better with a square point. When the penetration is less than 6 in at each blow the top of the pile should be protected from BROOMING by putting on an IRON RING, about 1 in less in diameter than the head of the pile, and from 2½ to 3 in wide by ⅝ in thick. The head should be chamfered to fit the ring. When driven into compact soil, such as sand, gravel, or stiff clay, the point of the pile should be SHOD with iron or steel. The method shown at *A*, Fig. 31, answers very well for all but very hard soils, and for these a CAST CONICAL POINT about 5 in in diameter, secured by a long DOWEL, with a RING around the end of the pile, as shown at *B*, makes the best shoe. Piles that are to be driven in or

exposed to salt water should be thoroughly impregnated with creosote, dead oil, or coal-tar, or some mineral poison to protect them from the TEREDO or SHIP-WORM, which will completely honeycomb an ordinary pile in three or four years.

Driving Wooden Piles with the Drop-Hammer. The piles should always be driven to an even bearing, which is determined by the PENETRATION under the last four or five blows of the hammer. The usual method of driving piles for the support of buildings is by a succession of blows given with a block of cast iron or steel, called the HAMMER, which slides up and down between the uprights of a machine called a PILE-DRIVER. The machine is placed over the pile, so that the hammer descends fairly on its head, the piles always being driven with the small end down. The hammer is generally raised by steam-power and is dropped either automatically or by hand. The usual weight of the hammers used for driving piles for building foundations is from 1 500 to 2 500 lb, and the fall varies from 5 to 20 ft, the last blows being given with a short fall. Occasionally, hammers weighing up to 4 000 pounds and over are used.

Driving Wooden Piles with the Steam-Hammer. Steam-hammers* are to a considerable extent taking the place of the ordinary drop-hammers in large cities, as they will drive many more piles in a day, and with less damage to the piles. The steam-hammer delivers short, quick blows, from sixty to seventy to the minute, and seems to jar the piles down, the short interval between the blows not giving time for the soil to settle around them.† In driving piles care should be taken to keep them plumb, and when the penetration becomes small, the fall should be reduced to about 5 ft, the blows being given in rapid succession. Whenever a pile refuses to sink under several blows, before reaching the average depth, it should be cut off and another pile driven beside it. When several piles have been driven to a depth of 20 ft or more and refuse to sink more than ½ in under five blows of a 1 200-pound hammer falling 15 ft, it is useless to try them further, as the additional blows only result in brooming and crushing the heads and points of the piles, and splitting and crushing the intermediate portions to an unknown extent.

Spacing Wooden Piles. Piles should be spaced not less than 2 ft nor more than 3 ft, on centers, unless iron, wooden, or reinforced-concrete grillage is used. When long piles are driven closer than 2 ft on centers there is danger that they may force each other up from their solid bed on the bearing stratum. Driving the piles close together also breaks up the ground and diminishes the bearing power. When three rows of piles are used the most satisfactory spacing is 2 ft 6 in on centers across the trench and 3 ft on centers longitudinally, provided this number of piles will carry the weight of the building. If they will not, then the piles must be spaced closer together longitudinally, or another row of piles driven; but in no case should the piles be less than 2 ft apart on centers, unless driven by means of a water-jet. The number of piles under the different portions of the building should be proportioned to the weight which they are to support, so that each pile will receive very nearly the same load.

Capping Wooden Piles. The tops of the piles should invariably be cut off at or a little below low water-mark, otherwise they will soon commence to decay. They should then be capped, either with large stone blocks, or concrete, or with timber or steel grillage.

Granite Capping. Wooden piles are sometimes capped with block-granite LEVELERS which rest directly on the tops of the piles. If the stone does not fit

* See Table XI, page 204.

† The 5 000 piles, averaging 48 ft in net length, under the Chicago Post Office were driven with a steam-hammer weighing 4 400 lb and delivering 60 blows per minute.

the surface of the pile, or a pile is a little low, it is wedged up with oak or stone wedges. In capping with stone a section of the foundation should be laid out on the drawings showing the arrangement of the capping stones. A single stone may rest on one, two, or three, but not on four piles, nor on three piles in a straight line, as in the two last-mentioned cases it is practically impossible to make the stones bear evenly. Fig. 32 shows the best arrangement of the capping for three rows of piles. Under dwellings and light buildings the piles are often driven in two rows, STAGGERED, in which case each stone should rest on three piles. After the piles are capped, large footing stones, extending in single pieces across the wall, should be laid in cement mortar on the capping. Fig. 33 shows a partial piling-plan, with the arrangement of the capping stones, of the Boston Chamber of Commerce Building. It may be seen that most of the stones rest on three piles, and a very few on two piles.

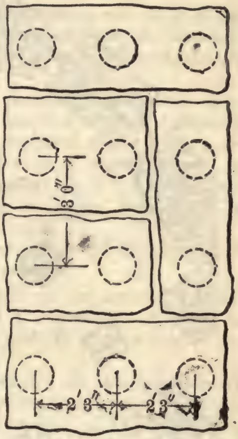

Fig. 32. Stone Capping for Three Rows of Wooden Piles

Concrete Capping. In New York City a very common method of capping is to excavate to a depth of 1 ft below the tops of the piles and 1 ft outside of them and to fill the space thus excavated solid with Portland-cement concrete, deposited in layers and well rammed. After the concrete is brought level with the tops of the piles additional layers are deposited over the whole width of the foundation until the concrete attains a depth of 18 in above the piles. On this foundation brick or stone footings are laid as on solid earth. If long bars of twisted steel, about ¾ in square in cross-section are embedded in the concrete about 3 in above the tops of the piles, the construction makes, in the opinion of the author, the best form of capping, the twisted bars giving great transverse strength to the concrete.

Timber-Grillage Capping. Most of the pile foundations of Chicago have heavy timber grillages bolted to the tops of the piles and stone or concrete footings laid on top of the grillages. The timbers for the grillages should be at least 10 by 10 in in cross-section, and should have sufficient transverse strength to sustain the load from center to center of piles, using a low fiber-stress. They should be laid longitudinally on top of the piles and fastened to them by means of DRIFT-BOLTS, which are plain bars of iron, either round or square in section, and driven into holes about 20% smaller in section than the bolts themselves. Round or square bars 1 in in section are generally used, the holes being bored by a ¾-in auger for the round bolts and by a ⅞-in auger for the square bolts. The bolts should enter the piles at least 1 ft. If heavy stone or concrete footings are used and the space between the piles and timbers is filled with concrete level with the tops of the timbers, no more timbering is required; but if the footings are made of small stones and no concrete is used, a solid floor of cross-timbers, at least 6 in thick for heavy buildings, should be laid on top of the longitudinal capping and drift-bolted to them. Where timber grillage is used it should, of course, be kept entirely below the lowest recorded water-line, as otherwise it will rot and allow the building to settle. It has been proved conclusively, however, that any kind of sound timber will last practically forever if completely immersed in water.

The Advantages of Timber Grillage are that it is easily laid and effectually holds the tops of the piles in place. It also tends to distribute the pressure evenly over the piles, as the transverse strength of the timber will help to carry

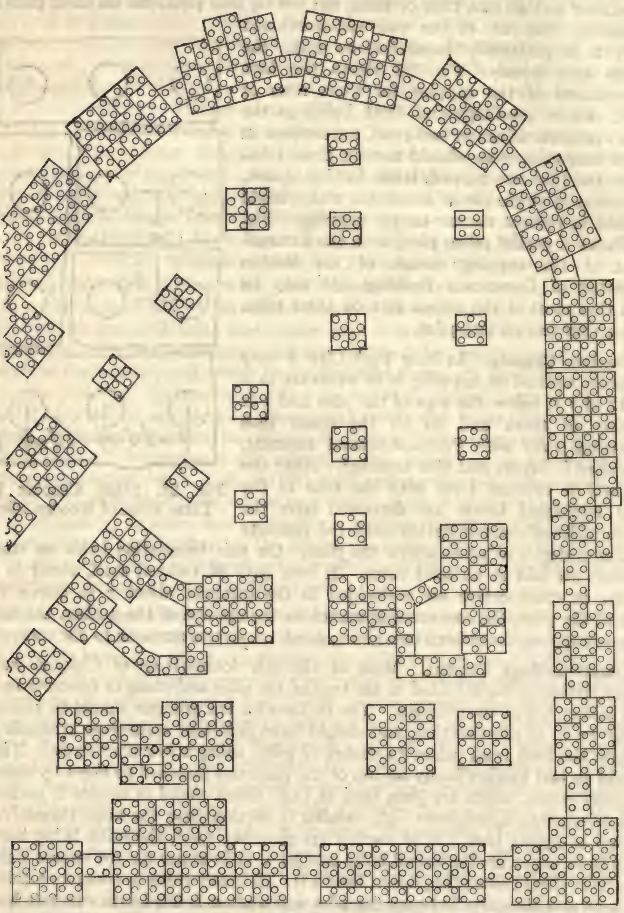

Fig. 33. Piling-plan, Chamber of Commerce Building, Boston, Mass.

the load over a single pile, which for some reason may not have the same bearing capacity as the others. Steel beams, embedded in concrete, are sometimes used to distribute the weight over piles, but some other form of construction can generally be employed at less expense and with equally good results.*

* For a description of the pile foundations and capping of the Chicago Post Office, see Freitag's Architectural Engineering, pages 350 to 352.

Specifications for Wooden-Pile Foundations. This contractor is to furnish and drive the piles indicated on sheet No. 1.

The piles are to be of sound spruce (hemlock, long-leaf yellow pine) perfectly straight from end to end, trimmed close, and cut off square to the axis at both ends.

They are to be not less than 6 in in diameter at the small end, 10 in at the large end, when cut off, and of sufficient length to reach solid bottom, the necessary length of piles to be determined by driving test-piles in different parts of the foundation.

All piles are to be driven vertically, in the exact positions shown by the plan, until they do not move more than 5 in under the last five blows of a hammer weighing 2 000 lb and falling 20 ft. All split or shattered piles are to be removed if possible and a good one driven in place of each imperfect one. In cases where such piles cannot be removed an additional pile is to be driven for each imperfect one. If the piles show a tendency to BROOM, they are to be bound with wrought-iron rings, 2½ in wide and ½ in thick.

All piles, when driven to the required depth, are to be sawed off square for a horizontal bearing at the grade indicated on the drawings.

The Bearing Power of Piles. In regard to their use for supporting buildings, piles may be divided into two classes: (1) Those which are driven to ROCK or HARD-PAN, that is, firm GRAVEL or CLAY and (2) those which do not reach HARD-PAN.

(1) A pile belonging to this class when driven through a soil that is sufficiently firm to brace the pile at every point, may be computed to sustain a load equal to the safe resistance to crushing on the least cross-section. If the surrounding soil is plastic the bearing power of the pile will be its safe load computed as a column, having a length equal to the length of the pile when capped. Test-piles driven on the site of the Chicago Public Library Building, through 27 ft of soft, plastic clay, 23 ft of tough, compact clay and 2 ft into hard-pan, sustained a load of 50.7 tons per pile for two weeks without apparent settlement. There are many instances where piles driven to the depth of 20 ft in hard clay sustain from 20 to 40 tons, and a few instances where they sustain up to 80 tons per pile.

(2) A pile belonging to this class depends for its bearing power upon the FRICTION, COHESION and BUOYANCY of the soil into which it is driven. The safe load for such piles is usually determined by the average penetration of the pile under the last four or five blows of the hammer. Several engineers have formulated rules for determining the safe loads for piles of this class, but there are so many conditions that modify the amount of the penetration, and its exact determination, and so many varying conditions of driving and of soil, that it is considered impossible to formulate any rule that can be considered entirely satisfactory for all the conditions under which such piles are driven.

The Engineering News Formula. The formula generally used by engineers was derived by M. A. Wellington, and is often referred to as the ENGINEERING NEWS FORMULA:

$$\text{The safe load in tons} = 2\,wh/\,(S + 1)$$

in which

w = the weight of the hammer in tons;
h = the height of fall of the hammer in feet;
S = the penetration in inches under the last blow or the average under the last five blows.

When loads are based on this formula the piles should be driven until the penetration does not exceed the limit assumed, or if this is found to be impracticable,

new calculations must be made based on the smallest average penetration that can be obtained, and a greater number of piles used. In localities where piling is commonly used for foundations, the least penetration that can be obtained within practical limits of length of pile can generally be ascertained by observation, or by consulting somebody who is experienced in driving piles. The longer the pile the less, as a rule, will be the final SET or penetration. Where there is no experience to guide one it will be necessary to drive a few piles to determine the length of pile required, or the least SET for a given length of pile. Some piles will have to be driven further than others to bring them to bearings of equal resistance. When the piles are to be loaded to more than 50% of the assumed safe load, the final set of each pile should be carefully measured by an inspector, the BROOM and SPLINTERS being removed from the head of the pile for the last blow.

Safe Loads for Piles. Table X, computed by the above formula, gives the safe loads for different penetrations, under different falls of a hammer weighing 1 ton. FOR A HAMMER OF DIFFERENT WEIGHT multiply the safe load in the table by the actual weight of the hammer in tons. Thus, for a hammer weighing 1 000 lb, the values in the table should be multiplied by ½ and for a 1 500-lb hammer, by ¾.

Table X. Safe Loads in Tons for Piles

For hammer weighing 1 ton

Penetration of pile in inches	Height of the fall of the hammer in feet

Example of Computations for Pile Foundation. Suppose that from the observations of the pile-driving for an adjacent building it is found that piles driven from 20 to 30 ft take a set of 1 in under a 1 200-lb hammer falling 20 ft, and that additional blows result in about the same set.

From Table X we find that the safe load for a fall of 20 ft and a penetration of 1 in is 20 tons. Multiplying by the weight of the hammer in tons, 0.6, we have 12 tons as the safe load per pile. Suppose that the total load on 1 lin ft of footing is 13 tons. As we must have at least two rows of piles, and each two piles will support 24 tons, it follows that the spacing of the piles longitudinally should be 24/13 = 1 ft 10 in. As this is too close, we should use three rows of piles, spaced 2 ft apart laterally, and the longitudinal spacing

would then be $36/13 = 2$ ft 9 in. The width of the capping would be about 5 ft. If the load on the piles under the interior columns, for example, is 105.8 tons, this, divided by 12, the safe load for one pile, gives nine piles, or three rows of three piles each, which should be spaced 2 ft 6 in apart, each way.

Some Actual Loads on Wooden Piles. The following examples of the actual loads supported by piles, under well-known buildings, and of loads which piles have borne for a short time without settlement, should be of value when designing pile foundations.

BOSTON. At the Southern Railroad Station three piles were loaded with about 60 tons of pig iron, 20 tons per pile, without settlement. The allowed load was 10 tons per pile.

Piles 12 in in diameter at the butt and 6 in at the point, driven 31 ft into hard, blue clay near Haymarket Square, failed to show movement under 30 tons, the ultimate load being probably 60 tons.* Other piles driven 17.9 ft sustained a load of 31 tons each. The average penetration under the last ten blows of a 1 710-lb hammer falling from 9 to 12 ft varied from 0.4 to 0.95 in per blow for fifteen piles.

Piles 25 ft long under the Chamber of Commerce Building penetrated about 3 in under the last blow of a 2 000-lb hammer falling about 15 ft.

CHICAGO. In the Public Library Building the piles were proportioned to 30 tons each and were tested to 50.7 tons without settlement.

In the Schiller Building the estimated load was 55 tons per pile; the building settled from 1½ to 2¼ in.

In the Passenger Station of the Northern Pacific Railroad, at Harrison Street, piles 50 ft long were designed to carry 25 tons each and did so without perceptible settlement.

The Art Institute Building, parts of the Stock Exchange Building and also a large number of warehouses and other buildings on the banks of the river rest on piles.

NEW YORK CITY. The Ivins (Park Row) Building is supported by about 3 500 14-in spruce piles, arranged in clusters of fifty or sixty, for single columns, and a corresponding number under piers supporting two or more columns. The piles were driven to refusal of 1 in under a 20-ft fall of a 2 000-lb hammer. The material is fine, dense sand to a depth of over 90 ft. But few piles could be driven more than 15 or 20 ft. The average maximum load per pile is 9 tons.†

The American Tract Society's Building is supported on piles.

BROOKLYN. Piles under the Government Graving Dock, driven 32 ft, on the average, into fine sand mixed with fine mica and a little vegetable loam, are supposed to sustain from 10 to 15 tons each.

NEW ORLEANS. Piles driven from 25 to 40 ft into a soft alluvial soil carry safely from 15 to 25 tons, with a factor of safety of from 6 to 8.‡

The Cost of Driving Wooden Piles. The cost of driving piles naturally varies with the character of the soil, and the conditions under which they are driven.

NEW YORK CITY. A 2 500-lb drop-hammer drove 4 piles per day of 10 hours. With a steam-hammer, 13 piles per day were driven, for the same foundation. The piles were 70 ft long, 8 in in diam at the point and 15 in at the head.

The average cost of driving 800 piles with the steam-hammer was $2 each. In New York Harbor 1 800 piles were driven by a steam-hammer, from 24 to 26 ft into gravel and hard-pan, at a cost of 80 cts each.

* Horace J. Howe, American Architect, June 11, 1898.

† For a description of this foundation, see the Engineering Record of July 23, 1898.

‡ W. M. Patton.

CHICAGO. Forty Norway-pine piles were driven by a firm of contractors 15 ft deep every ten hours at a cost, for driving, of 55 cts each. Another firm drove from 60 to 65 piles, each 45 ft long and 15 ft deep, into hard sand each day at a cost of about 30 cts each. In both cases steam-hammers were used.*

BOSTON. Spruce piles from 30 to 45 ft long cost from $3 to $5, in place. Long-leaf yellow pine piles, as long as 70 ft, cost about $15 apiece for the piles themselves, and $2 or more each for the driving. Oak piles from 40 to 50 ft long cost from $8 to $10 each, in place.†

Some Other References to Wooden Piles and Pile-Driving. A very valuable paper on "Some Instances of Piles and Pile-Driving, New and Old," by Horace J. Howe, was published in the American Architect and Building News, commencing June 11, 1898. The paper records a great many tests and gives several formulas and many experiences of distinguished engineers. Part I of Building Construction and Superintendence, by F. E. Kidder, gives additional information in regard to pile foundations and experiments on the bearing power of piles. Much valuable information on piles is given in "A Practical Treatise on Foundations," by W. M. Patton. The recent Engineers' Handbooks, also, should be consulted for additional data.

28. Concrete-Pile Foundations

Durability of Wooden and Concrete Piles. Concrete piles, either plain or reinforced, possess many advantages over wooden piles and, in general, can be used in all places where wooden piles can be driven. Concrete piles, compared with wooden piles, have primarily the advantage of greater PERMANENCE. Timber piles, kept constantly wet and protected from the action of the TORREDO or other destructive influences, may be practically everlasting, but cannot be counted upon above water level; whereas concrete piles should be proof against all deteriorating actions, whether wet or dry, except the action of freezing on wet concrete.

Strength of Wooden and Concrete Piles. Concrete piles without reinforcement, if made of good concrete, should have nearly the same CRUSHING STRENGTH per square inch as ordinary yellow-pine piles, and with properly placed reinforcement concrete piles should have a much higher crushing strength per square inch than timber piles. Moreover, timber piles do not have UNIFORM CROSS-SECTIONS. For instance, a slender timber pile 40 ft in length and 12 in in diameter at the butt, is probably not over 6 in in diameter at the point. In direct compression the load on a point-bearing pile of the above dimensions is limited to the safe load on the point of the pile, where it is 6 in in diameter; and a cylindrical concrete pile, 12 in in diameter and under similar conditions, will have a cross-section of 113 sq in at all points, compared with the cross-section of 28 sq in at the point of the timber pile. Moreover, if we consider both piles as LONG COLUMNS, it must be borne in mind that a timber pile may not be straight and that it may, therefore, be subject to STRESSES and DEFORMATIONS due to ECCENTRIC LOADING, which are avoided in a straight, concrete pile.

Reinforced-Concrete Piles. In practice concrete piles are generally reinforced, and if a pile is to be considered as a long column the reinforcement may be increased at the center, so as to provide for stresses due to handling and to its acting as a long column. The concrete piles may be formed complete, above ground, in which case they may be straight or tapered, with square, circular or other cross-sections. The reinforcement may consist of a number of

* American Architect, June 4, 1898, page 78.

† George B. Francis, in American Architect, July 23, 1898.

vertical rods generally disposed symmetrically around the axis of the pile. The vertical rods should be connected by horizontal wiring or by spiral reinforcement. As before stated, the reinforcement may be increased at the central section so as to provide against stresses due to the use of the pile as a LONG COLUMN, in which case the additional reinforcement should be placed near the periphery of the cross-section.

Types of Concrete-Pile Reinforcement. There are many TYPES OF REINFORCEMENT, one method even employing a woven-wire fabric which is laid out flat on a table and covered with a thin layer of concrete, the entire mat comprising the wire fabric and the concrete being then rolled into a solid cylindrical form which, when set, forms the finished pile. The concrete piles may be FORMED IN PLACE by any one of several different methods.

The Raymond Method of Forming Concrete Piles in Place. In the so-called RAYMOND PILE METHOD a steel MANDREL of tapered form is driven into the ground, and when the required penetration has been obtained this mandrel is collapsed and withdrawn, leaving a hole corresponding to the size of the extended mandrel in the ground; this hole is then filled with concrete. The reinforcement may be placed in the hole prior to the placement of the concrete. This method, as described, is applicable only to such material as will stand while the mandrel is being withdrawn and the hole is being filled with concrete. In most cases the method used is as here described except that a thin shell of steel is placed on the mandrel before driving. When the mandrel is collapsed the shell is left in the ground, thus forming a lining for the hole which is subsequently filled with concrete or with reinforcing-rods and concrete, as before described. Raymond piles have been extensively used, especially for FRICTION-PILES or SKIN-BEARING PILES in soft and artificially filled-in ground. An improved form of lining-shell recently employed in the Raymond method is combined with a spiral reinforcement inside of the shell, which materially assists in preventing the collapse of the shell.

The Simplex Method of Forming Concrete Piles in Place. THE SIMPLEX METHOD differs from the Raymond method and may be briefly described as follows: A steel pipe, generally cylindrical in form, of the required size and length and fitted with a detachable cast-iron conical DRIVING-POINT, is driven into the ground to the required depth; the pipe is then partially filled with concrete. A piston-like PLUNGER, smaller in diameter than the inside diameter of the pipe, is then placed on the concrete and the pipe is partially withdrawn, leaving the driving-point and part of the superimposed concrete in the ground. This operation is repeated until the pile is built up to the required height. In certain materials, instead of using a detachable driving-point, the driving-point consists of two jaws hinged to the lower end of the pipe, so arranged that while during the driving they form a driving-point, when the pipe is withdrawn they open and form an extension of the cylindrical pipe. In other words, the jaws are formed of steel plates previously bent to the same radius as the radius of the pipe and so hinged that when they are in their open-position the plates forming the jaws constitute an extension of the cylindrical surface of the pipe. It is evident that plain reinforcing-bars can be placed in position before concrete is put into the pipe.

Caution for Concrete Piles Built in Place. Care should be taken in designing and placing the reinforcing for all concrete piles BUILT IN PLACE, that the subsequent placing of the concrete does not throw the reinforcement out of position and that all voids between the reinforcement and the shell are completely filled.

The Pedestal Pile is designed to give an ENLARGED CROSS-SECTION at the base of the pile. The method is similar to that of the RAYMOND METHOD, the increase in diameter being obtained as follows: After the pipe has been driven, the driving-core is withdrawn and the pipe partially filled with concrete. Then the concrete in the pipe is rammed, forcing the concrete out of the pipe and compressing the material below the pipe, so that the concrete is forced into the soil. A repetition of this operation results in forming a BASE or MUSHROOM below the pipe larger in diameter than the diameter of the pipe. Finally the pipe is withdrawn, the filling and ramming-operations continuing meanwhile, until the pile is carried up to the required height.

Composite Piles. Protected piles, for use in localities where the TORREDO affects the life of timber piles under water, are composed of timber piles with concrete coatings held in position by steel reinforcements in the shape of expanded metal or wire netting. Such piles are to be considered as timber piles rather than as concrete piles.

Timber Piles with Concrete Caps. In some localities where the permanent water-level is considerably below the level of the required excavation, timber piles have been driven with a FOLLOWER, the follower consisting of a steel pipe or cylindrical shell. When the head of the pile is driven to a safe distance below low water the PIPE-FOLLOWER is filled with concrete and withdrawn, leaving the concrete pier resting on a timber pile. This composite pile would appear to possess the advantage of combining the cheapness of a timber pile below the water-level with the permanency of a concrete pile above the water-level. Great care, however, should be used in adopting this method on account of the difficulty of securing proper connection between the concrete and the wooden pile.

The Methods used in Driving Built-up Piles are practically the same as are used in driving wooden piles, except that a CUSHION of wood, rope, or other material is placed on the head of the pile to be driven to cushion the blow of the hammer. Steam-driven or air-driven RECIPROCATING HAMMERS are preferable to the ordinary DROP-HAMMERS. In stiff materials the use of a WATER-JET is advisable and, in fact, in many cases indispensable. In lifting concrete piles use is made of a special SLING which is attached to a pile at two points, each point one-quarter of the length of the pile from the end. The sling should have a SPREADER so that the stress due to the oblique pull of the CHAIN-SLING is taken up by the spreader rather than by the pile.

The Casting of Concrete Piles. Concrete piles should be CAST IN ONE PIECE by a continuous operation so that there will be no PLANE OF WEAKNESS formed between partially set concrete and fresh concrete. They may be cast either in a vertical position, in forms, or in a horizontal position. Square-section concrete piles have been cast in a horizontal position and side-forms, only, used, the previously cast concrete pile, protected by paper, forming the bottom form. In some cases, where it is intended to use a WATER-JET in sinking a pile, the latter is cast around an iron pipe which is afterwards used for the water-jet. In general, however, this is dispensed with and an external detachable pipe used for the water-jet.

Incidental Advantages of Concrete Piles. In many cases, where concrete piles are more expensive than timber piles, the saving in excavation and footings more than offsets the increased cost. For example, if the excavation for the cellar of a building does not go down to water-level, the use of timber piles will necessitate excavating down to a point below water-level in order that the piles may be cut off low enough to keep their heads always wet. Concrete

piles, however, can be driven from the level of the bottom of the cellar-excavation, and this additional excavation and the necessary construction between the excavation-level and the level of the cut-off for the timber piles thus avoided. Moreover, as one concrete pile may have a SUPPORTING POWER equal to the supporting power of four wooden piles, the size of the footings will be much smaller with concrete piles than with wooden piles.

Comparison of Wooden and Concrete Piles under Piers. The footings for a column or pier 24 in sq in section, requiring for its support, say, sixteen wooden piles, spaced 2 ft 6 in from center to center, will be, allowing for slight inequalities in driving, approximately 10 ft square, the projections being 4 ft beyond the size of the base. Such a footing will ordinarily require a steel grillage or reinforced-concrete base, or, if made of ordinary concrete, will be of very considerable depth; whereas, if four concrete piles, placed 3 ft from center to center, are used, instead of wooden piles, the area of the base will be a little over 4 ft square and the projection will be only 1 ft. A suitable footing would consist of a reinforced-concrete cap not over 2 ft in thickness. The saving in cost of excavation, concrete and steel in the footing is all in favor of the use of concrete piles.

Concrete Piles under Walls. In the case of a continuous wall, where the load per linear foot of wall is not great, a single row of concrete piles is often sufficient to support the weight of the wall. In such cases, the piles should not be placed in straight lines but should be STAGGERED, and a sufficient footing should be constructed connecting the heads of the piles, so as to afford stability to the wall.

The Method Employed in Calculating Reinforcement for Concrete Piles is the same as that employed in calculating ordinary reinforced-concrete columns, the only difference being that where a pile is not point-bearing, but is dependent on the surrounding material for its support, it need not be considered as a LONG COLUMN. POINT-BEARING PILES deriving their support from some solid material on which their lower extremity rests, must be considered as LONG COLUMNS, on the assumption that the material surrounding the piles may fail to support them. In the case of FRICTION-PILES, depending for their support upon the surrounding material, this assumption cannot be made, as any failure of the material will involve a settlement of the pile. It should be borne in mind that any structure supported on piles supported by SKIN-FRICTION is dependent for its stability upon the continued supporting power of the material surrounding the piles. In many cases buildings resting on piles driven into soft ground have settled as the result of the consolidation and settlement of the material surrounding the piles, notwithstanding the fact that the piles when driven were amply able to support the loads for which they were designed.

Iron-Pipe Piles with Concrete or Reinforced-Concrete Filling have been used in place of wooden or concrete piles, especially in UNDERPINNING-WORK. The objection to the use of such piles is that the iron pipe forming the external shell may rust, in which case the strength of the pile is reduced to the strength of the concrete filling and the reinforcement contained therein. The writer believes that they should not be used for permanent work.

Loads Allowed on Concrete Piles. The building laws of most cities allow on concrete piles from 350 to 500 lb per sq in on the concrete plus from 6 000 to 7 500 lb per sq in on the vertical reinforcement. On this statement it would appear possible to design a short concrete pile 12 in square, on which the allowed load would be 100 tons, and it is possible that such a pile, tested as a SHORT COLUMN, would develop in a testing-machine a strength justifying

the use of such construction; but, bearing in mind that the character of the support for the base of such a column is underground and cannot be inspected, and bearing in mind also the uncertainties attending the manufacture of the pile, it is evident that it would be improper to load a pile to this extent in practice. It would, however, be considered good practice to load concrete piles up to one-third of a test-load applied to not less than 3% of the piles used. In ordinary practice, reinforced-concrete piles are loaded up to 500 lb per sq in of cross-section.

29. Foundation Piers and Foundation Walls

Foundation Piers and Walls as distinguished from ordinary CELLAR PIERS and WALLS, extend from the level of the underside of the cellar-floor to rock or other solid foundation-bed. (See page 129, Subdivision 1, and also Chapter III, pages 228–9.) In general, such piers and walls are composed of concrete and are of such dimensions that the safe unit loads on the concrete forming them are not exceeded. If the foundation-bed is rock, compact hard-pan, or gravel, there need be little or no enlargement of the base of the pier or wall, as the safe unit loads on such natural foundation-beds are generally equal to the safe unit loads on the concrete forming the body of the pier or wall. The design of such piers and walls is therefore an entirely simple matter governed by the principles already outlined, and by certain considerations mentioned hereafter.

The Methods used in the Construction of Foundation Piers and Walls are, however, necessarily varied to suit different materials and to meet different conditions encountered, and the design of a pier necessarily differs with different methods of construction. For example, if the construction is to be executed by means of the ordinary SHEET-PILING METHOD, piers and walls will have in general rectangular outlines. But if the CHICAGO METHOD or the PNEUMATIC CAISSON is employed, it will generally be cheaper to use piers having a circular cross-section and the support for walls may be a succession of cylinders rather than continuous walls. The detailing of the concrete structure constituting the piers or walls is simple after a determination is made of the methods by which the construction is to be put in place. This subject is discussed in the following chapter-subdivision, Methods of Excavating for Foundations.

30. Methods of Excavating for Foundations

Simple and Complex Excavations. Excavations in earth for footings of walls and piers may vary from simple trenches and pits of the required sizes and depths to accommodate the footings, up to deep subaqueous excavations requiring all the resources of engineering skill.

The Sides of Excavations. If the earth is firm and the depth not excessive the sides of the excavation may be self-supporting, in which case the excavation may be made the neat size of the footing and the sides of the excavation may take the place of forms for the concrete deposited to form the footing. Where the excavation is deep, and especially where the earth is not firm, the sides of the excavation must be sloped or, if made vertical, must be supported by bracing or by some form of sheet-piling. Where the excavation is over 8 ft in depth it will generally be cheaper to support the sides of the excavation than to slope them. Where the excavation adjoins a property-line it will generally be inadvisable to slope the excavation on account of damage to the adjoining property, and in such cases it will be necessary to use sheeting, even if sloping the earth would be cheaper.

Bracing in many cases will serve to support the sides of the excavation without the necessity of close SHEETING. The BRACING may consist simply of short pieces of PLANK placed against opposite sides of the excavation and held in position by horizontal timber STRUTS secured by WEDGES; or, especially in narrow trenches, some form of an EXTENSIBLE SEWER-BRACE may be used. Fig. 34 represents a usual form of EXTENSIBLE BRACE. Generally, however, the sides of an excavation will not stand with a vertical face, even if braced in this manner, for any length of time, and if the material is loose sand or soft clay, such bracing is entirely inadequate. In such cases, and in fact generally, some form of CONTINUOUS SHEET-PILING must be employed.

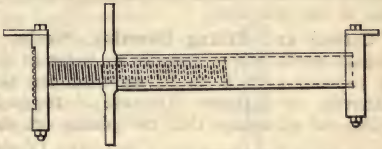

Fig. 34. Extensible Brace for Narrow Excavations

Ordinary Wooden Sheet-Piling consists of a continuous line of vertical planks held against the sides of the excavation by horizontal timbers known as WALES, WALING or BREAST-TIMBERS, these wales, or breast-timbers being in turn supported either by CROSS-BRACES extending across the excavation to an opposite wall or side of the excavation, or by inclined struts known as SHORES or PUSHERS, extending to the bottom of the excavation where HEELS or inclined platforms are sunk in the undisturbed material to afford points of support.

Earth-Pressure on Sheet-Piling. The load on the sheeting due to the EARTH-PRESSURE may be calculated on the assumptions made for the design of RETAINING-WALLS, but the thickness of the sheeting planks, the sizes and spacing of the breast-pieces and braces, if figured on this basis, will in general exceed the sizes constantly used with success and safety in such work. The probable reason for this is that an earth bank, when steadied and in part supported by the sheeting, does not, for a considerable time, lose the COHESION between its particles natural to most earth banks in their original and undisturbed state. Or, in other words, under these conditions no real ANGLE OF FRICTION is developed in the earth-mass. Local experience and practice should be consulted and will generally serve as a guide. Earth banks apparently similar will, however, act very differently and no general rule can be given. It should be borne in mind that the earth composing a bank should be, as far as possible, protected from jar, from the action of water and from alternating freezing and thawing; and that permanent work should be completed as rapidly as possible so as to avoid the deteriorating effects of time and exposure on the structure of the bank.

The Thickness of the Sheeting Planks required may be calculated on the assumption that the earth bank is composed of loose material having a definite ANGLE OF SLOPE and COEFFICIENT OF FRICTION; but practically, under favorable conditions, 2-in planks may be used for a depth of drive of 16 ft, 3-in planks up to 24 ft and 4-in planks up to 32 ft; and timbers, 8 by 12 in, have been driven in favorable material to a depth of over 40 ft.

Depths and Numbers of Drives. Ordinarily the depth to which a plank can be driven is limited by its ability to resist the shock due to driving, and in unfavorable material a plank may become shattered before it is driven to the above-quoted depths. If the required depth cannot be reached by the first planks or DRIVE, a second, and sometimes a third and fourth set of planks are employed. As the BREAST-PIECES supporting the first line of planks must remain in place,

the planks in the second set or DRIVE have to be placed inside of the breast-pieces, thus reducing the size of the excavation by the amount of the necessary offset. Where more than one drive is required the first drive should be started at a sufficient distance outside to allow the planks forming the second or the second and third drives to be placed outside of the required area for the bottom of the excavation.

Cutting and Fitting Sheeting Planks. The sheeting planks may be SQUARE-EDGED where there is no water or fine loose sand, but where water or running sand is to be excluded the planks should be TONGUED AND GROOVED, or SPLINED. The use of tongued and grooved planks has the additional advantage that the planks are more readily kept in line. It is

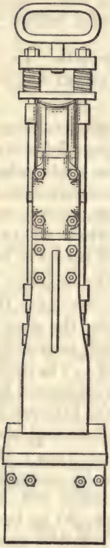

Fig. 35. Small Power-hammer for Driving Sheeting Planks

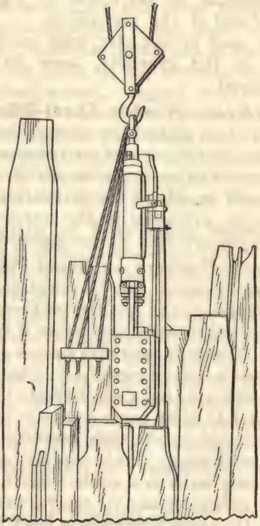

Fig. 36. Large-size Power-hammer and Sheeting Planks

usual to cut the bottom edge of each plank on a slight angle, so that in driving it is WEDGED against the preceding plank. The top of each plank may be fitted to receive an iron DRIVING-CAP; or, if this is not used, the upper corners of the plank should be cut off so that the effect of the blows will be concentrated along its vertical axis, and the tendency of the plank to SPLIT, due to a blow on one corner, thus diminished.

The Means Employed for Driving the Sheeting vary with the depth and the size of the sheeting. For small jobs and for moderate depths of drive, the primitive method of DRIVING BY HAND with ringed wooden MAULS still prevails. For work involving a considerable amount of driving, and in all cases for long drives, POWER-HAMMERS driven either by steam or compressed air are preferably employed. A small-sized power-hammer (Fig. 35) resembles a STEAM-DRILL and may be handled by two or three men without any special lifting-

appliances. The larger sizes of power-hammers (Figs. 36 and 37) are practically small, power, pile-driving hammers arranged with a special DRIVING-HEAD to fit the sheeting employed. Such hammers are handled by DERRICKS or are carried in a frame similar to a pile-driver frame. Ordinary DROP-HAMMERS are sometimes used, but are not as advantageous as the RECIPROCATING POWER-HAMMERS, as the blow struck by the drop-hammer shatters the plank, while the frequent light blows of the power-hammer tend to keep the planks and the adjacent material in motion and accomplish the required work with less damage to the sheet-piling. The weights and dimensions of several types of pile-driving hammers are given in Table XI, page 204.

Manner of Driving Sheeting Piles. In practice, a shallow excavation is first made to the proper line for the outside of the sheeting planks. The top BREAST-TIMBER is temporarily secured in place and the lower end of the planks placed between this timber and the bank. If the planks are long, temporary TOP GUIDES or STAY-BRACES are arranged so as to keep the planks vertical until they have been driven well into the ground and guided by the permanent BREAST-PIECES. The planks are then driven as the excavation progresses, each plank being driven a few inches in turn. As the driving goes on the material under the lower edge of the planks is loosened with a shovel or with a crowbar, the operation being so conducted that the planks are held true to line. The horizontal breast-timbers and their braces are placed in position as the excavation progresses. If inclined braces are to be used the excavation in the center is taken out first, leaving a sloping bank against the sides of the excavation. This permits of the placing of the inclined braces and of the heels for their points of support before there is any danger to the bank. After the first breast-piece and its inclined brace are set in place, the second and subsequent breast-pieces and braces are put in as the excavation proceeds.

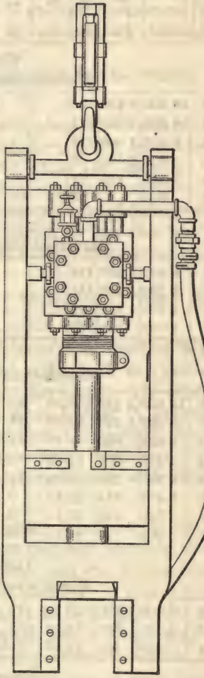

Fig. 37. Large-size Power-hammer for Driving Sheeting Planks

Sheet-Piling for Excavations Below Water-Level. These excavations may be made by the SHEET-PILING METHOD if there is not too much water and if water can be drained out of the material without inducing a flow of sand or clay below the bottom of the sheet-piling. In some cases, where unfavorable conditions exist, but where there is an underlying stratum of impervious material, it is possible to drive the sheeting in advance of the excavation, so that the bottom of the sheeting makes a tight joint with the impervious stratum, cutting off the flow of water and material. Where a considerable amount of water finds its way into the excavation, the water must be led to a SUMP or depression from which it is ejected by means of a PUMP or a STEAM-SYPHON. Where the foundation-bed is below water-level and the material is sand, clay, or other material which would be softened by the action of the water, it should be protected by having the sump at a considerable distance from the area to be used for the sup-

port of the footing. This may be accomplished by making the area to be sheeted and excavated large enough to accommodate the sump outside of the supporting area, or by sinking a separate excavation to be used exclusively as a sump; or the same result may in some cases be accomplished by the use of DRIVE-WELLS, driven to a point below the level of the footing in which continued pumping may reduce the level of the water to a point below the footing. Care also should be taken, when the level for the footing is reached, to prevent the foundation-bed from being disturbed and softened by unnecessary tramping of workmen over the surface of the excavation.

The foundation-bed should be left as nearly as possible in its original or natural condition.

Steel Sheeting has been largely employed recently in place of wooden sheeting. It has the advantage that it can be driven in advance of the excavation, thereby reducing the likelihood of any flow of material under the sheeting. It also has the advantages of affording greater strength for a given thickness of sheeting, of being driven to a greater depth, and in many cases of being withdrawn and used over again. As generally manufactured, it has the further advantage of being INTERLOCKING, so that there is less danger of its getting out of line and leaving openings between adjacent pieces.

All of these advantages have been considered by engineers in using steel instead of wooden sheeting.

The Use of Steel Sheeting. The fundamental idea of steel sheeting is not new, as CAST-IRON SHEET-PILING was used in England as far back as 1822 and various combinations of steel plates have been used in coffer-dams. The general use of steel sheeting started in this country in 1899 when Luther P. Friestedt drove experimental INTERLOCKING CHANNEL-BAR SECTIONS. Since that time it has come into general use, and with its aid many excavations have been made with STEEL SHEET-PILING which would have been impracticable with timber sheeting.

Earth-Pressure on Steel Sheeting. In using STEEL SHEETING, it should be borne in mind that the EARTH-PRESSURE coming on the steel sheeting is the same as the earth-pressure coming on timber sheeting, and the breast-pieces and braces should be as strong as in the case of timber sheeting. Certain forms or sections of steel sheeting offer considerable resistance to bending due to the lateral earth-pressure. With such forms the horizontal breast-pieces may be spaced farther apart than with ordinary timber sheeting or steel sheeting not having this property; but the strength of the breast-pieces and of their braces must be sufficient to take up the entire load coming on the sheeting, irrespective of the spacing between such breast-pieces, for in case there is a failure in these the entire sheeting will fail.

Different Forms of Steel Sheeting. Various TYPES OF STEEL SHEETING are on the market. In making a selection between different forms of sheeting, the character of the material to be encountered should be borne in mind, as the simpler, more compact sections will penetrate hard or gravelly soils with less danger of deformation than the more complicated sections made up of thin plates and shapes. The various companies manufacturing different forms of sheet-piling publish catalogues containing data as to the weight and also giving the properties of the different sections. These catalogues may be obtained from the manufacturers, but for convenience illustrations of some of the principal sections, with their dimensions and weights and other details, are given in the following pages.

There are other types of steel sheeting than those shown in Figs. 38 to 44.

The Poling-Board or Chicago Method is a special method of excavation in general use in Chicago and in occasional use elsewhere for excavations which go to a great depth in clay or in other suitable material. It has the advantage over the ordinary sheet-piling method that the lining of the excavation is not driven. The method is not generally used for trenches or for square excavations as a circular excavation is more readily handled. The success of the method depends entirely upon the character of the material to be encountered, as the excavation is first made and the sides of the excavation afterwards supported. The method in detail for a circular excavation for a pier-foundation may be described as follows:

(1) A circular excavation slightly in excess of the size required for the pier is carried down to a depth of 5 ft, great care being taken to have the sides of the excavation vertical and true to the circle.

(2) Vertical planks called LAGGING-PIECES, 5 ft in length and slightly beveled on their edges so that each piece may be considered as a stave with radial joints corresponding to the size of the required circle, are set in place against the walls of the excavation. These planks are held in place by two or more steel rings, generally made in quadrants, so that they may be conveniently handled and bolted together. The planks are wedged firmly against the walls of the excavation by means of wooden wedges driven between the planks and the iron rings.

(3) As soon as the first set of lagging is complete, the excavation is carried down for another section, 5 ft in depth, and another section of lagging is put in place and secured in the same manner.

Depth and Character of Excavations in the Poling-Board Method. In the manner described above the excavation may be carried down for an indefinite distance, a depth of 100 ft having frequently been attained. In many cases the bottom of the excavation is BELLED OUT to a larger diameter than the excavation for the main shaft of the pier with the object of reducing the load of the foundation-bed to a unit load less than the safe unit load on the main shaft of the pier. This method is not adapted for running sand nor for clay that is not solid enough to stand with vertical sides during the necessary interval between making the excavation and placing the lagging. In some cases where a stratum of quicksand has been encountered, the excavation has been carried past it

by the use of a cylindrical shell of steel, forced by jacks through it to an underlying impervious layer of clay; but in general this method is dependent for its success upon a continuous body of impervious material.

The Open-Caisson Method or Well-Curb Method is used for piers to be carried to a considerable depth, and has advantages over the sheet-piling method in certain materials. It is a development of the old method used in sinking masonry wells and, in its modern form, consists of a structure which eventually forms part of the pier itself and which is arranged with an open chamber at its base in which men may excavate the material under the structure and allow it to settle as the excavation proceeds. It is evident that a central opening or shaft must be left in the structure to permit of the passage of men and material.

Details of the Open-Caisson Method. In detail, the method may be described as follows: First a CURB or CUTTING-EDGE of timber or steel, following the outline of the pier, is constructed on the surface of the ground. The outer face of this curb is generally vertical and is protected with a steel plate which extends below the main section of the curb, so as to form a cutting-edge or sharp downward projection serving to penetrate the soil slightly in advance of the excavation. On this curb a wall of timber, concrete, or masonry is constructed, inside of which the so-called WORKING-CHAMBER affords room for the workmen to be employed in excavating. Above the working-chamber the walls may continue to a height corresponding to the required height of the pier, leaving the central space to be filled in after the required depth is reached; or a roof may be built over the working-chamber and the entire cross-section of the pier filled with concrete or masonry excepting only a small central opening large enough to accommodate a HOISTING-TUB or BUCKET and to permit of the ingress and egress of the men employed in sinking the construction. In practice, the excavation is started before the pier-structure is carried up to its final height, after which the excavation and the building up of the pier progresses simultaneously, the constantly increasing weight of the structure aiding the sinking of the pier. When the excavation has reached rock or a firm substratum, further excavation is stopped and the working-chamber and the central opening are packed full of concrete, leaving finally a complete pier-structure extending from the rock to the proper level to receive the steel grillage or other construction coming on the pier.

Advantages of the Open-Caisson Method. This method of construction has the advantages that the workmen at all times are protected, that obstructions, such as boulders or logs, may be removed from under the cutting-edge, and that when rock is encountered, ample opportunity is afforded for the proper preparation of the rock-surface to receive the final concrete filling. If a moderate amount of water is encountered, not accompanied by a flow of material, it can generally be taken care of by means of pumps.

Dredged Wells are similar to the open caissons described in the previous paragraphs and are used where large quantities of water are encountered. The construction of the piers is similar to that of the piers used in the open-caisson method; but the central shaft and working-chamber are designed to permit of the use of a CLAM-SHELL DREDGE or other form of dredge, and the water is allowed to rise to its natural level in the working-chamber and shaft. This method can be used to advantage when a considerable amount of water-bearing sand or other material is found overlying level rock or other firm foundation-bed. When the dredging and the sinking of the pier-structure have been carried down to the hard underlying strata it is sometimes possible to pump out the water. If this is not practicable the bottom may be prepared by divers for the reception of the concrete filling, and the concrete may be deposited through water,

care being taken to use some special arrangement to protect the concrete from being injured by loss of its cement-content, in the process of deposition.

The Well-Digger's Method is also occasionally used in making PIT-EXCAVATIONS under walls or in cramped locations. By this method the sides of the excavation are supported by planks placed horizontally. The method of placing the planks is as follows: A shallow excavation, the depth of a plank, is made by ordinary methods, and a SET, consisting of four planks fitting the four sides of the excavation, is secured in place. Before proceeding with the general excavation of the pit a trench is dug directly alongside and underneath one of the side planks of the FIRST SET. As soon as this trench is deep enough to accommodate the planks for the SECOND SET, the side of the trench under the plank already in place is cut to a vertical face, the plank placed in position and the loose earth temporarily back-filled against it. As soon as the four planks forming the SECOND SET have been put in place by this method, the two side planks are wedged against the bank, the end-planks being used as struts. The end-planks are wedged into position and nailed or cleated to the side planks forming a PRESSURE-RESISTING FRAME supporting the side of the excavation. A continuation of this method enables the excavation to be carried on indefinitely, provided there is no flow of water or run of material causing an inflow of material into the excavation.

The Pneumatic-Caisson Method. Where piers or foundation walls have to be carried to a considerable depth through water-bearing materials, and especially where large bodies of quicksand are encountered, the PNEUMATIC-CAISSON METHOD must be resorted to. This method is based upon the PRINCIPLE OF A DIVING-BELL and may be briefly described as follows: The construction of the pier is similar to the piers previously described as used in the open-caisson and dredged-well construction, except that the working-chamber and shaft are made air-tight and connected with a device called an AIR-LOCK, so that compressed air may be introduced into the working-chamber. The object of the compressed air is to prevent water entering into the working-chamber. This is accomplished in accordance with the well-known PRINCIPLE OF THE DIVING-BELL by having the compressed air constantly kept at a pressure which will counterbalance the water-pressure at the level of the cutting-edge of the working-chamber. The pressure of the air evidently must vary with the depth of the cutting-edge below water-level. A column of water 1 in square in cross-section weighs .43⅓ lb per vertical ft, and it will therefore be counterbalanced by an air-pressure of .43⅓ lb per sq in over the normal air-pressure. If the column of water is 30 ft in height, it will weigh thirty times .43⅓ lb, or will be counterbalanced by an air-pressure of 13 lb per sq in above the atmospheric pressure.

The Maximum Air-Pressure in the Pneumatic Caisson in which men can work for short periods is about 43 lb per sq in above atmospheric pressure, corresponding to a depth below water-level of about 100 ft. At this depth the work is carried on in shifts of from two to three hours duration, and great care must be exercised in coming out of the AIR-PRESSURE. The physiological effects of compressed air are often serious; pains in the joints, damage to the ear-drums resulting in deafness, and the so-called CAISSON-DISEASE render work at high pressure extremely hazardous.

The Air-Lock Used in Connection with the Pneumatic Caisson is a device for the purpose of retaining the air in the caisson and at the same time permitting the passage of men and material in and out. It consists essentially of a metallic AIR-TIGHT CHAMBER or SHELL connected to the working-chamber either directly or to an air-tight lining or extension of the central shaft-opening. This air-chamber has two doors, one at the bottom, opening downward into the shaft

and the other in the upper head of the air-lock chamber, also opening downward and affording a direct connection to the open air. In the operation of an air-lock one of these two doors must at all times be closed so as to prevent the free escape of air through the air-lock. If the bottom door is closed, it will be held firmly to its seat by the uplift of the compressed air in the shaft, which is at all times in direct communication with the working-chamber. If, under these conditions, the upper door is open, the interior of the air-lock will be in direct communication with the open air and the air contained in the lock will evidently be at atmospheric pressure. Workmen and materials may then enter the air-lock. In order to pass into the shaft and working-chamber, it is necessary, first, to close the upper door, and secondly, to shift the so-called EQUALIZING VALVE and admit compressed air into the space between the two doors, until the air-pressure is brought up to the air-pressure in the working-chamber and shaft. Pressure on the upper side of the lower door will then equal the pressure on the lower side and the lower door may be opened, the upper door being firmly held against its seat by the compressed air in the air-lock. As soon as the lower door opens, the men and material may be passed into the shaft and working-chamber. In coming out the operations are reversed; men and material enter the air-lock through the open lower door, the lower door is closed and held tightly against its seat, and the equalizing valve is shifted, affording a connection between the interior of the air-lock and the external air. The compressed air escapes through the equalizing valve, reducing the pressure in the air-lock to atmospheric pressure, and the upper door has atmospheric pressure on both sides of it. It may then be opened, giving free connection with the outside air.

The Design of Pneumatic Caissons. The first consideration is, of course, to have the final structure a permanent and sufficient pier to carry the load to be imposed upon it. To this end the cross-section of the pier at all points from top to bottom should be capable of carrying safely the maximum load. As the cross-section of the pier is generally, in the finished pier, composed of solid concrete, the cross-section will be determined by the allowable load on the concrete. For piers the cross-section will generally be square or circular; for walls the caisson will generally be not less than 6 ft in width, as it is difficult to sink caissons having a width less than 6 ft. If the caisson is to be carried to solid rock, the bearing on the rock need be no larger than the cross-section of the concrete pier; but if the excavation does not go to rock, it is frequently desirable to BELL OUT the base of the pier so as to reduce the loading on the foundation bed to a unit load less than that allowable on concrete. The operation of BELLING OUT is difficult in some materials; in a compact material it can be generally accomplished without serious difficulty.

Piers Sunk by the Pneumatic-Caisson Method may be constructed of various combinations of materials. The side walls and roof of the working-chamber were formerly frequently constructed of timber. In many cases they are now formed of steel; but in recent designs the working-chamber is generally formed of reinforced concrete, the only structural steel used being an angle or a plate and angle composing the cutting-edge. The outside of the caisson is preferably made vertical. The superimposed pier is generally of the same size as the working-chamber, at least it is generally so in piers sunk for buildings.

A Typical Design for a Caisson Built of Reinforced Concrete is given in Fig. 45, in which *AB* is the angle-iron and plate forming the so-called CUTTING-EDGE and *C* is the WORKING-CHAMBER formed by the side walls *DE* and *DE* and by the roof *EE*. The concrete side walls are reinforced with steel rods attached to the cutting-edge, and extending upward into the body of the pier, and the roof and body of the pier are reinforced to take care of stresses due to construc-

tion and sinking. In building up the working-chamber, the INTERIOR FORMS are arranged so as to support the concrete which makes the roof. These are subsequently removed. The exterior forms may constitute a permanent part of the structure, in which case they are called a COFFER-DAM, or they may be removed as soon as the concrete has sufficiently set. At the center of the pier an opening is left to serve as the SHAFT or opening connecting the working-chamber with the AIR-LOCK. The sides of this opening or of the upper part of it, only, are lined with an AIR-TIGHT STEEL SHELL. To the upper end of the steel shell the air-lock is connected. If the height of the pier does not exceed 40 ft the construction of it may be completed before the excavation is commenced. Generally, however, the construction of the pier is stopped as soon as the working-chamber and from 5 to 10 ft of the superimposed pier has been constructed; then sufficient excavation is done, without the use of compressed air, to carry the cutting-edge down to water-level. This is called DITCHING THE CAISSON and is done so that the caisson will have some slight lateral support from the soil before the construction is carried up high enough to make it top-heavy. When the entire pier or the first section is finished, excavation is resumed and the whole structure is sunk as the excavation progresses, care being taken to remove any obstruction from beneath the cutting-edge. During the progress of sinking compressed air is conducted to the working-chamber through the SUPPLY-PIPE *G*, the excavated material being hoisted through the SHAFT *F*. The shaft *F* is fitted with a LADDER for the use of the workmen.

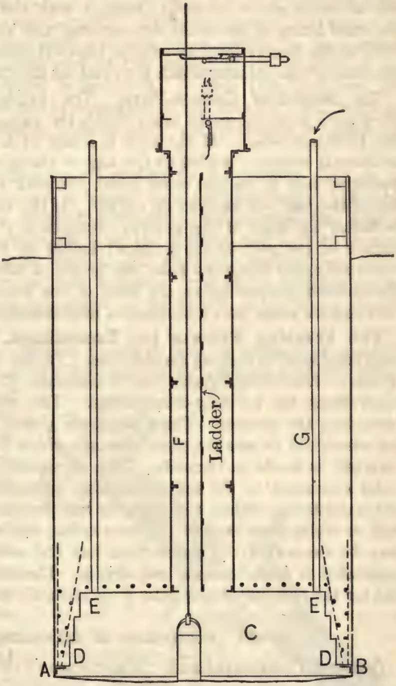

Fig. 45. Typical Form of Reinforced-concrete Caisson

Details of Caisson-Sinking and Filling. In sinking the caisson and superimposed pier, care must be taken to maintain it in a vertical position. This end may be accomplished in large caissons by means of the excavation itself. In case one side of the caisson is high the excavation on that side will be carried somewhat in advance of the excavation on the low side, and the material under the cutting-edge of the high side will be removed while a bank of material is kept under the cutting-edge of the low side. These methods, however, are of little avail when the caisson is narrow. In such cases that part of the caisson which is above ground is held in position by GUIDES or other devices; but it

frequently happens that the caisson in its final condition is considerably out of its correct location and considerably out of plumb. In general, therefore, the size of the caisson should be made larger than the minimum size necessary, in order to allow for errors in its final location. When the caisson has reached the required depth the foundation-bed is prepared for the reception of the concrete filling and the working-chamber filled with it, care being taken that it completely fills all voids and is in perfect contact with the roof. Finally, the air-lock and the steel lining of the shaft are removed and the shaft-opening filled with concrete to the proper level to receive the GRILLAGE or other construction forming the base of the column which is to rest on the caisson.

The Height of Caisson-Piers. The height of a pier cannot be exactly fixed until it is known to what depth the caisson must sink in order to reach the foundation-bed. If the rock is found at a greater depth than anticipated, additional height is added to the top of the pier after the caisson is in its final position; but if, on the other hand, the rock is found unexpectedly high, the top of the pier will have to be cut off. If the finished elevation of the pier is to be below the level of the general excavation, it is usual to extend the exterior surface of the pier to the required height by means of a temporary chamber-structure called a COFFER-DAM, the height of which corresponds to the depth of the finished surface below the level of the general excavation. Inside of this COFFER-DAM some STEEL GRILLAGES may conveniently be set.

The Freezing Process for Excavations. This method has sometimes been employed in making excavations. In this country its use has been limited to one or two mining-shafts, but in Germany it has been resorted to in making excavations for building-foundations. The method consists in driving steel pipes into the ground. These pipes are closed at the bottom and at the top are connected to smaller pipes through which brine, at an extremely low temperature, is made to circulate. The refrigerating effect results in freezing the water contained in the soil, converting quicksand to a frozen mass resembling soft sandstone. When the freezing has progressed sufficiently to form a solid wall or coffer-dam around the excavation, the material inside the frozen wall may be excavated. This method has the advantage, theoretically, of being applicable to excavations of any depth. There are many precautions necessary, and for the present, at any rate, it should only be considered as a possibility.

31. Protection of Adjoining Structures

General Considerations. The COMMON LAW provides that any person making an excavation is responsible for resulting damage to adjoining property. STATUTE LAWS as embodied in the building codes of different cities may modify or limit this responsibility, but in general, excavations should be made in such a manner as to cause the least possible damage to surrounding property. Where there are no adjoining structures it is generally sufficient to slope the sides of the excavation so as to prevent the sliding of material into the excavation, or, at least, to sheet-pile and brace the sides of the excavation; but where the excavation is to be made alongside of an existing structure, and carried below the footings of such structure, it is necessary to take special measures for its protection. Such work is described as SHORING, UNDERPINNING and PROTECTING ADJOINING STRUCTURES, and may involve the carrying of the weight of part or all of the buildings on temporary supports, the removal of the old footings and the construction of new footings at lower elevations.

Shoring. When the excavation for the new building does not go much below the adjoining footings and when the material is fairly solid, it may suffice to transfer a portion of the load of the wall to temporary footings. This may be

accomplished by means of heavy inclined posts called SHORES, arranged to act as INCLINED COLUMNS or STRUTS. Each SHORE consists of a post, the lower end of which rests on a PLATFORM, generally consisting of planks and timbers arranged so as to form a temporary spread footing. This platform should be placed at a depth which will insure that subsequent operations will not undermine it. The upper end of the post fits into a hole or niche cut into the wall to be supported. The post itself may be a timber with a square cross-section, usually 12 by 12 in, and of the required length. Provision is made, between the platform and the lower end of the post, for WEDGES or JACKS, so that when operated their lifting effect transfers part of the weight of the wall from its footing to the temporary foundation or platform. During this operation all parts of the temporary structure are in compression and brought into bearing, and the material under the platform is compressed and solidified as much as possible.

Kinds of Shores. If the SHORE is to act preferably for LIFTING only, it is kept as nearly vertical as possible and is known as a LIFTING SHORE. If it is to act preferably to combine a horizontal PUSHING action with the lifting action, it is placed at a considerable angle from the vertical and is then known as a PUSHING SHORE or STEADYING SHORE. In arranging such shores care should be taken to have the niche cut close to a floor-level of the building to be shored, as otherwise the horizontal component of the thrust of the shores might buckle the wall.

Numbers and Sizes of Shores. Where a wall is light, a number of smaller shores should be used in preference to a few large ones. Where a wall is high, two or more shores of varying lengths may be used, and these may conveniently be placed in the same vertical plane and rest on the same platform.

Wedges and Screw-Jacks. In transferring the load of a wall from its own footing to the temporary platform, use is made of wooden or steel WEDGES, SCREW-JACKS, or HYDRAULIC JACKS; or, wedges and jacks may be used in combination. Wooden wedges should be made of hard wood and are generally arranged in pairs, both wedges being driven at the same time. The lifting effect of such wooden wedges is powerful, but where a considerable settlement of the temporary foundation is anticipated, it is more convenient to use screw-jacks, as they can take up a considerable settlement.

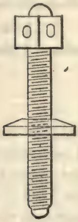

Fig. 46. Standard Type of Steel Screw-jack

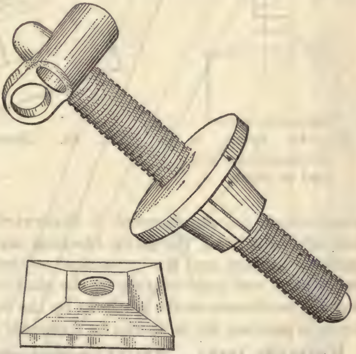

Fig. 47. Standard Type of Steel Screw-jack

Materials and Types of Screw-Jacks. The SCREW-JACKS usually manufactured for this purpose are made of cast iron and have rough threads, with too coarse a pitch to have much lifting effect. Screw-jacks of a better kind are made of steel and have a machine-thread of small pitch. Such jacks can be obtained capable of lifting weights up to 100 tons. Figs. 46 and 47 represent

standard forms of screw-jacks. When a single screw-jack is used in connection with a post or shore, a hole to receive the threaded portion of the jack is bored in the end of the timber used for the shore, the end being squared to receive the nut. Such an arrangement is called a PUMP and is illustrated in Fig. 48. When a lifting effect greater than that exerted by a single jack is required, the jacks are arranged in pairs in connection with a short timber or CROSS-

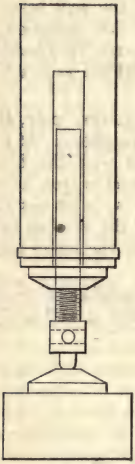

Fig. 48. Pump, or Screw-jack let into End of Shore

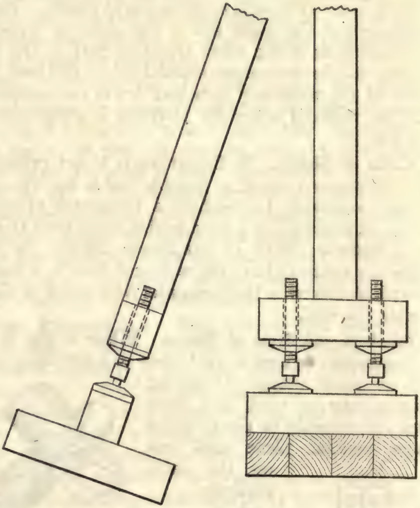

Fig. 49. Shore, Screw-jacks and Timber Cross-head

HEAD. Such an arrangement is illustrated in Fig. 49. It has the advantage that after operating the jacks, blocking and wedges can be placed between the platform-timbers and the cross-head so that the post resting on the cross-head has a direct and solid bearing on the platform. By this method the load of the wall can be thrown on the platform by the jacks and after the blocking and wedging is in position the jacks can be removed.

Hydraulic Jacks. Where excessively heavy loads are to be lifted, HYDRAULIC JACKS may be used in place of screw-jacks but an objection to them is that they are liable to SLACK BACK under the load. While the load, therefore, should not be permanently supported on hydraulic jacks, they may be used to take the load temporarily while the blocking and wedging are being placed between the cross-head and the temporary footing. In this way an indefinite number of shores may be set and taken care of with a single pair of hydraulic jacks.

Example of Shoring. Fig. 50 shows the method used in SHORING the ornamental front wall of a heavy building, advantage having been taken of the numerous deep margin-drafts shown in the section. In order to avoid the necessity of cutting niches for the tops of the shores, nine hardwood blocks, *a*, *a*, etc., were fitted to the margin-draft grooves in the masonry. Nine similar blocks, ***b***, ***b***, etc., were gained into and bolted to the vertical timber *VV*, space being

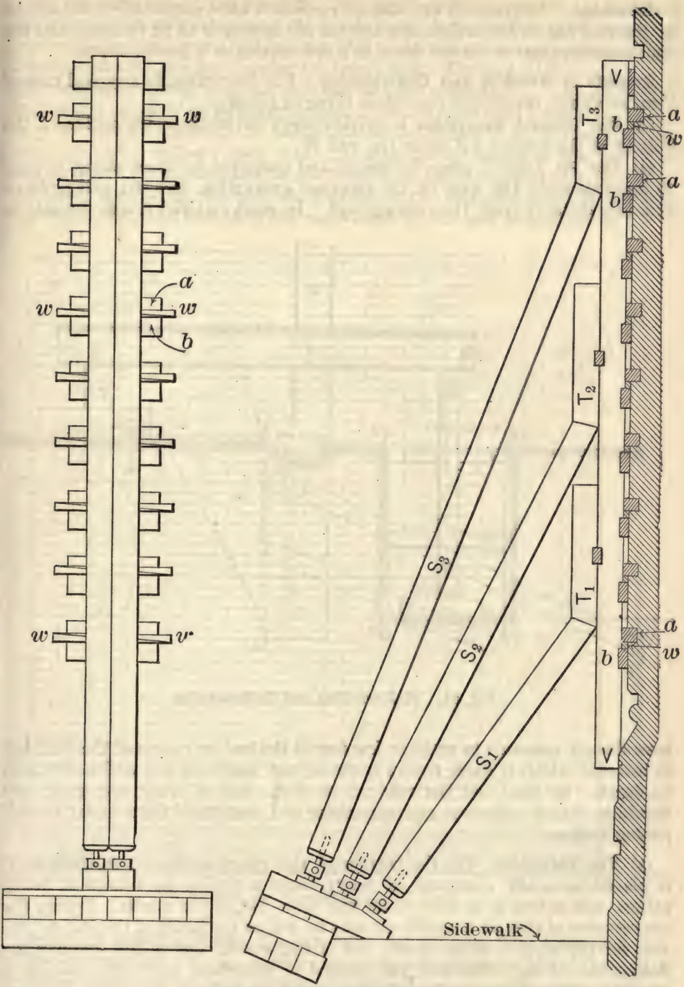

Fig. 50. Shoring an Ornamented Wall

left between the a blocks and the b blocks for adjusting wedges w, w, etc. Three headpieces, T_1, T_2 and T_3 were keyed and bolted to VV and transmitted to it the uplift of the three shores, S_1, S_2 and S_3. Each shore had a 60-ton screw-jack at its base. Each shore is shown fitted with a pump or detached extension-piece arranged for the screw-jack.

Needling. NEEDLES or GIRDERS are employed when part or all of the weight of the wall has to be carried, as when the old footing is to be removed and the wall UNDERPINNED or carried down to a new footing at a greater depth.

Example of Needling and Underpinning. Fig. 51 represents a typical case of UNDERPINNING, the several operations being as follows:

(1) **The General Excavation** is carried down to within a few inches of the bottom of the footing *BB* under the wall *W*.

(2) **The Pit** *DDDD*, properly braced and protected by sheet piling, is sunk to approximately the level of the proposed excavation, this PIT being placed at a safe distance from the existing wall. In good material it may be safe to

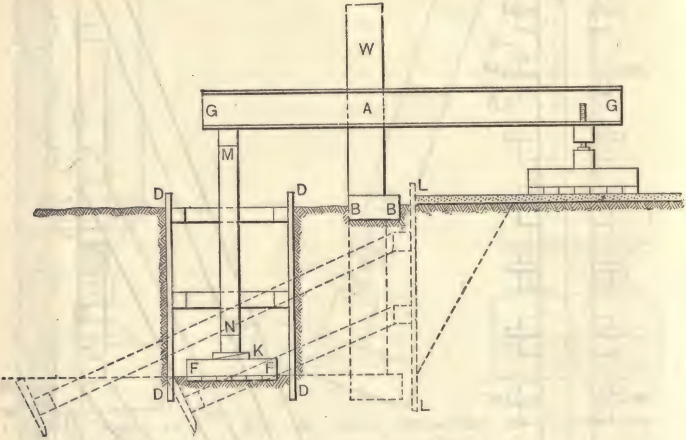

Fig. 51. Wall-needling and Underpinning

have this pit approach to within a few feet of the footing course of the wall, but in material which is liable to run it should not approach the wall closer than its depth. No hard and fast rule can be given, and in every case great care should be taken to prevent any movement of the material from under the adjoining footing.

(3) **The Platforms.** On the bottom of this pit-excavation, a PLATFORM *FF* is placed, generally composed of heavy timbers resting on a base of heavy planks, and acting as a support for the outer end of the needle. During the construction of this pit a similar pit may be dug on the inside of the wall to provide for the support of the inside end of the needle; but as this involves the destruction of the cellar-floor the method of procedure inside the building is generally different from this. If the material is solid it is sometimes sufficient to place the platform for the support of the inside end of the needle directly on the cellar-floor and at such a distance from the wall that the necessary excavation for the new footing will not disturb it; or the platform may be placed on the cellar-floor and a line of sheeting *LL*, properly braced, so placed that the excavation can be made for the new footing. This is generally sufficient to prevent any serious settlement of the temporary platform for the inside end of the needle.

(4) The Insertion of the Needles. Having provided a support for each end of the NEEDLE it only remains to cut a hole through the wall, as at A, insert the needle GG, put the post and blocking MN under the outside end of the needle, and the blocking and jacks under the inside end. The post MN may be fitted with wedges as shown at K, or with one or more screw-jacks. The needle GG may consist of one or more heavy timbers or one or more steel **I** beams. In any case, the load to come on this needle should be figured and its strength made ample to safely support such load. As soon as the weight of the wall W is transferred to the needles and to the temporary platforms prepared to receive the load, that part of the wall which is below the needles and all of the footing may be removed and all of the excavation for the new footing made.

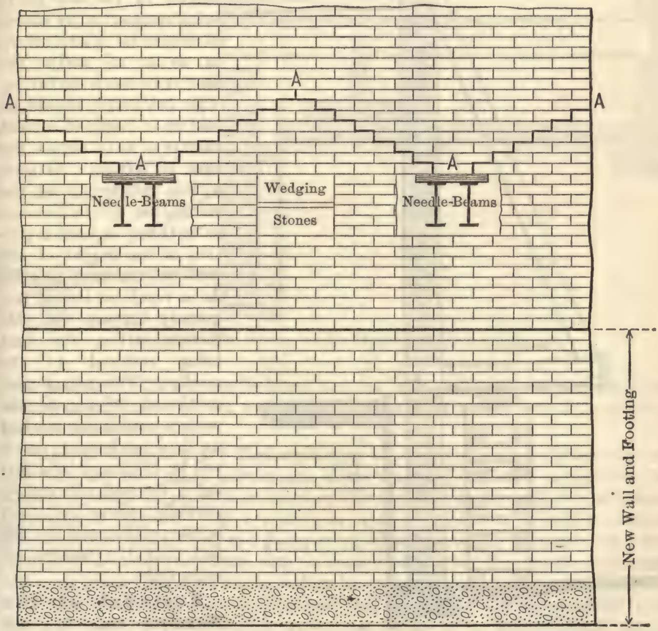

Fig. 52. Needling a Brick Wall

Needling a Brick Wall. Fig. 52 shows the elevation of a brick wall supported by NEEDLES. If the needles are carrying the entire weight of the wall, it is evident that at the level of their upper surfaces the entire weight will be transferred through those parts of the wall which are immediately above them, and that above these points the material composing the wall will CORBEL OUT in both directions as indicated in Fig. 52 by the heavy zigzag lines $AAAAA$. All of the wall below this line will be supported simply by COHESION to the part of the wall above it. An experienced man can determine the location of this line by the sound given by the wall on being struck by a hammer. All of the wall below this line is HANGING and liable to fall as soon as the support given by

the footing is removed. The hanging parts of the wall may be removed or suspended by rods and chains to the needles. If they are not so suspended a crack will form along the line *AAAAA*.

Transferring the Load to the New Underpinning. As soon as the new footing has been put in place and the new wall carried up ready to receive the old wall, provision must be made for REVERSING THE OPERATION, that is, for transferring the load onto the new underpinning wall and footing. This is generally done by means of a number of GRANITE BLOCKS set in pairs between the needles and fitted with STEEL WEDGES. After setting these blocks, the space between the base of the old wall and the top of the upper wedging block is filled in with brickwork, the mortar in the last joints being compacted by means of PIECES OF SLATE driven in so as to wedge the mortar between the bricks. This brickwork should be laid up in Portland-cement mortar so as to reduce the time of setting. As soon as it is sufficiently set, the wedges are driven home so as to throw at least a portion of the weight of the wall on the new footing. As a result of this it frequently happens that this footing settles, the load being restored to the needles. This necessitates continued driving on the wedges until it has reached its final settlement, which will be evidenced by a lifting of the wall sufficient to partially relieve the stress in the needles and by the fact that the wedges remain tight.

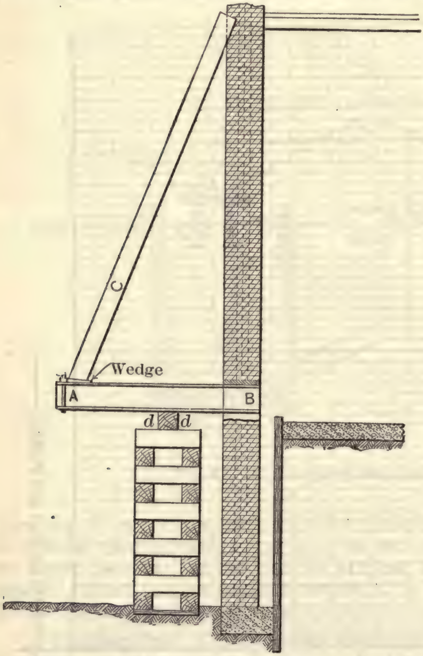

Fig. 53. The Figure-four Method of Needling

Removal of the Needles, etc. As soon as the entire weight of the wall has been transferred to the footing and the footing has demonstrated that it is capable of supporting the weight of the wall without further settlement, all of the temporary work, including the needles, can be removed, the needle-holes bricked up and the repairs made to the cellar of the adjoining building.

The Figure-Four Method of Needling. In certain cases it is impractical to employ a NEEDLE-BEAM projecting on both sides of the wall, as for example when the occupancy of the adjoining building is such as to make it impractical to have a needle-beam projecting into the cellar space. In such cases the so-called FIGURE-FOUR NEEDLE has been employed (Fig. 53). In this case the needle *AB* acts as a CANTILEVER. Part of the load of the wall is carried by the

inclined shore *C* and another equal or nearly equal part is carried by the needle at *B*, the needle-beam *AB* being really balanced on the block *dd*.

Spring-Needles. Fig. 54 shows a method frequently employed, known as the SPRING-NEEDLE METHOD. In this case the needle engages with the wall to be supported and also with an adjoining wall. A temporary platform is placed as close to the wall to be supported, *W*, as is practicable. The uplift of the

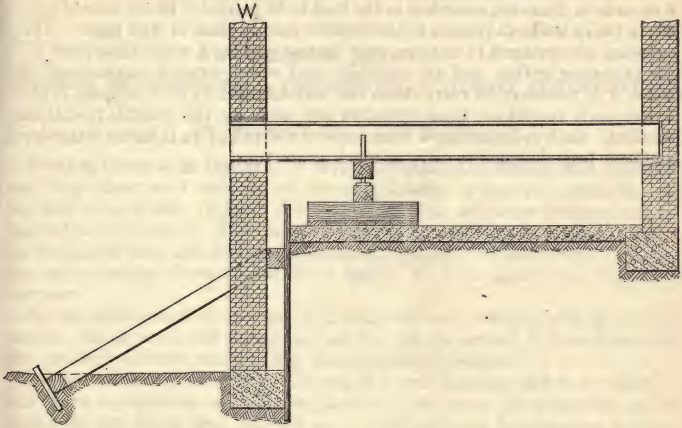

Fig. 54. The Spring-needle Method of Underpinning

jack tending to lift the needle-beam acts on both walls, but on account of its being located nearer to the wall to be lifted, a large proportion of its effect is exerted thereon.

Pipes or Cylinders for Underpinning are frequently used for the support of a wall and have many advantages, as they not only afford a support for the footing through the operations affecting the stability of the wall, but also form a permanent support. The operation in brief is as follows: A hole or niche is cut in the wall and footing to be supported, of sufficient size to permit the introduction of a section of STEEL PIPE, in such manner that the center of the pipe will come below the center of the wall to be supported, the height being sufficient to accommodate a section of pipe and also the means employed to drive it. The pipe may be driven (1) by HYDRAULIC JACKS or by SCREW-JACKS, placed between the top of the pipe and the wall itself, as by the patented BREUCHAUD METHOD; (2) it may be driven by means of a POWER-HAMMER driven either by steam or compressed air; or (3) in some cases, where the material is fine sand or clay, the pipe may be JETTED or the JET-METHOD may be used in combination with either jacks or power-hammers. In any case the first section of pipe is driven into the ground and additional sections are added until the lower end of the pipe encounters rock or some material possessing sufficient stability to insure the required support. The material entering the pipe is removed by a WATER-JET or by other means and the space filled with concrete. As soon as the concrete has set sufficiently the pipe is capped with a special casting on which short steel **I** beams are arranged to distribute the support of the pipe over a considerable part of the base of the wall to be supported. These **I** beams correspond

to the wedging blocks used in the ordinary methods before described. Provision is frequently made for STEEL WEDGES between the cap and the base of the steel beam, but it is generally found sufficient to thoroughly grout in the space between the base of the wall and the steel beams after the niche itself has been bricked up.

Cylinders for Underpinning Very Heavy Walls. The description in the preceding paragraph is intended to cover the use of pipes varying in size from 6 to 20-in in diameter, according to the load to be carried. In the case of excessively heavy walls, CAST-IRON CYLINDERS are used in place of steel pipes. These cylinders are arranged in sections, each section making a water-tight joint with the preceding section, and are generally used where water is encountered and where it is necessary to carry down the underpinning to rock at great depths. Under such conditions these cylinders are sunk by the PNEUMATIC-CAISSON METHOD. Such cylinders have been sunk to a depth of 70 ft below water-level and have been designed to carry as much as 400 tons.

CHAPTER III

MASONRY WALLS. FOOTINGS FOR LIGHT BUILDINGS.* CEMENTS AND CONCRETES

BY
THOMAS NOLAN
PROFESSOR OF ARCHITECTURAL CONSTRUCTION, UNIVERSITY OF PENNSYLVANIA

1. Footings for Light Buildings

Footing Courses in General.† Every foundation or bearing wall overlying anything except solid rock should rest on a footing or base projecting beyond the wall on each side. On wet or very compressible soils these footings may be built of steel beams or of reinforced concrete, as described in Chapter II, but on reasonably firm soils and for buildings of moderate size and weight the footings are generally of concrete, stone, or brick. Footings answer two important purposes:

(1) By distributing the weight of a structure over a larger area of bearing surface, the pressure per square foot on the foundation-bed is diminished and the tendency to vertical settlement correspondingly lessened.

(2) By increasing the area of the base of a wall, footings add to its stability and form a protection against the danger of the work being thrown out of plumb by any forces that may act on it. Nearly every building law requires that every foundation wall or pier and every cellar or basement wall or pier shall have a footing at least 12 in wider, that is, 6 in on each side, than the thickness of the wall or pier, and this may be considered as the minimum projection, except in rare instances where there may be a special reason for making it less. On firm soils and for comparatively light buildings a projection of 6 in on each side of a wall will generally reduce the unit pressure, that is, the pressure per square foot, to the safe resistance of the soil, but it is always wise to proportion the footings to a uniform unit pressure, as explained in Chapter II, Subdivision 8. To have any useful effect, footings must be well bedded and have sufficient transverse strength to resist the upward reactions on the projections.

Stone Footings for Walls with Ordinary Loads. Stone cellar walls and basement walls generally have stone footings, although if the walls are heavily loaded a bottom footing of coarse concrete is advisable under the stone footing. If practicable, stone footings should consist of stones having a width equal to that of the footing. If impracticable to obtain stones of this size, then two stones should be used, meeting under the middle line of the wall. In any event each footing course should extend inside of the course above, a distance equal to at least one and one-half times the projection, otherwise the stones will not properly transmit the loads and reactions and the footing courses will tend to open at the joints, as in Fig. 1.

* For a complete discussion of foundations in general and the mechanical principles involved in their strength and stability, for walls, piers, etc., below the basement or cellar floor, see Chapter II.

† For a complete discussion of footing courses for heavy buildings and of the theories of the stresses developed in offset, projecting, or cantilever footings, see Chapter II, especially Subdivisions 17 to 23.

Stone footings should be of hard, strong and durable stones, always laid on their natural bed and solidly bedded in mortar. As a general rule, for light buildings, and where the loads per unit of foundation-bed are much less than the allowable pressure, the thickness of each course is made about equal to its projection beyond the course above. The most common defect in large-stone footings is that the stones are not properly bedded, as it is more difficult to bed a large stone than a small one. The stones should be laid in a thick bed of mortar and worked sidewise with a bar until firmly settled in place.

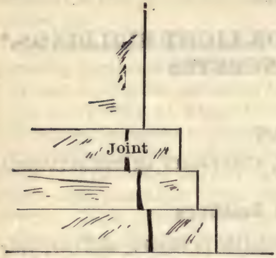

Fig. 1. Stone Footing. Openings at Joints

Offsets in Masonry Footings.* The projections of the footing courses beyond the wall, or beyond the courses above, must be carefully considered, whatever the material of the footings. If the projection of the footing or offset of the courses is too great for the strength of the stone, brick, or concrete, the footing will crack, as shown in Fig. 2. The proper offset for each course depends upon the vertical load, the transverse strength of the material, the resisting power of the foundation-bed and the thickness of the course.†

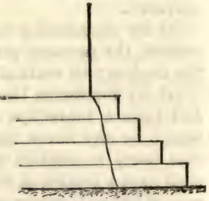

Fig. 2. Crack in Footing from Excessive Offsets

Tables for Offsets for Masonry Footing Courses.‡ As stated in Chapter II, in the discussion of the design of stepped footings, there are rule-of-thumb methods giving so-called safe projections for given depths of footings or giving the ratios between the projections and the depths of the courses. Tables of offsets for footing courses of different materials have been computed from the flexure-formula applied to the projecting footing courses considered as CANTILEVER BEAMS uniformly loaded by the upward pressures on the under side. Although these tables, so computed, are incorporated in some building codes, they cannot be safely used without numerous restrictions, exceptions and modifications, and hence they are, in general, unreliable and of use only as approximations. As these tables are still inserted in engineers' and architects' handbooks, the table of offsets for masonry footing courses, in a revised form, is retained in this chapter with the recommendation that for footings of several offsets it be used with caution and that for such footings the methods explained in Chapter II be used when greater accuracy of results is required.

Notes Regarding Use of Table I. The values in Table I are computed from the formula $l = \frac{1}{6} d \sqrt{S_f/wf}$ which is derived from the FLEXURE-FORMULA for a uniformly loaded cantilever beam, and slightly changed to make the numerical coefficient of the second member of the equation the value shown.§ In this equation, l = the maximum allowed offset of the footing course in inches, d = the thickness of the footing course in inches, S_f = the modulus of rupture

* See Offset Footings, Chapter II, especially Subdivisions 17 and 22.

† See Chapter II, Subdivision 22, for a complete discussion of the principles involved in the design of projecting footings, ratio of projection to depth of footing, etc., for homogeneous slabs, separate-layer footings, etc.

‡ See Chapter II, Subdivision 22, page 180.

§ See, also, formula in Chapter II, Subdivision 22.

Table I. Approximate Values of Offsets for Masonry Footing Courses in Terms of the Thickness of the Course

The values are computed with a factor of safety of 10.

Material of the footings	S_f in pounds per square inch	w in tons per square foot		
		0.5	1.0	2.0
North River Bluestone (ordinary run)	3 000	4.1	2.9	2.0
Granite (average)	1 850	3.2	2.2	1.6
Limestone (average)	1 375	2.8	2.0	1.4
Sandstone (average)	1 375	2.8	2.0	1.4
Brickwork (good bricks in natural-cement mortar, 1 : 2, 60 days old)	125	0.8	0.6	0.4
Brickwork (hard-burned bricks in Portland-cement mortar, 1 : 3, 60 days old)	400	1.6	1.1	0.7
Concrete (Portland cement, 1 : 2 : 4, 1 month old)	300	1.3	0.9	0.6
Concrete (Portland cement, 1 : 2 : 4, 6 months old)	400	1.5	1.1	0.7

of the materials in pounds per square inch, w = the determined or assumed pressure on the bottom surface of the footing course considered, in tons of 2 000 lb per sq ft, and f = the factor of safety used. The table gives the values of l/d for three unit pressures w. For example, if w is taken at 2 tons per sq ft, then for limestone or sandstone footings $l/d = 1.4$, and if d, the thickness of the footing course, is 12 in, the offset or projection should be 16 or 17 in. The values given in the table for S_f, the modulus of rupture for the materials, differ very slightly from those given in Subdivision 22 of Chapter II, in Table I of Chapter XV and in Table III of Chapter XVI. If results are required based upon different fiber-stresses, upon a different factor of safety, or upon different pressures per square foot, the formula may be used instead of the table. It should always be borne in mind that as each footing course transmits the entire weight of the wall and its load, the pressure will be greater per square foot on the upper courses, and that the offsets should be made proportionately less; and that the values in Table I, when applied to stone-masonry footings, are really valid for the lower offset only, and then only when the footing is built of stones the thickness of which is equal to the thickness of the course, which have a projection of less than half their length, and which are well bedded in cement mortar.

Concrete Footings.* For buildings of great weight, except the very heaviest, and especially for those built on a clay soil, concrete generally makes the best footing, and it is even preferable to and generally cheaper than large slabs of stone. When the concrete is properly made and used, it attains a strength equal to that of most stones, and under walls, being devoid of joints, it is like a CONTINUOUS BEAM, having sufficient strength to span any soft spots that happen to be in the foundation-bed. When deposited in thin layers and well rammed, concrete becomes firmly bedded on the bottom of the trenches, so that there is no possible chance for settlement except that due to the compression of the soil.

* For an example of concrete-footing design, see Chapter II, Subdivision 22. For reinforced-concrete-footing design, see Chapter II, Subdivision 24. See, also, Chapter XXV, paragraphs relating to footings, pages 978 to 982.

Preparing the Trenches. For footings, concrete made with Portland cement is preferable, and it should have a thickness of at least 8 in, even under light buildings; and for buildings of more than two stories, a thickness of at least 12 in. On firm soils, such as hard clay, the trenches should be accurately dug and trimmed to the exact width of the footings, so that the concrete will fill them. When the foundation-bed is of loose gravel or sand it is generally necessary to set up planks to confine the concrete and form the sides of the footings. These planks may be held in place by stakes; they should be left in place until the concrete has become hard, which generally requires from two to four days, after which they may be pulled up and dirt filled in against the concrete. The proportions and manner of mixing concrete are described in the latter part of this chapter.

Depositing the Concrete. Concrete should be used as soon as mixed and should always be deposited in layers, which as a rule should not exceed 6 in in thickness, especially for the first layer. On small jobs where the work is done by hand the concrete is usually carried to the trenches in wheel-barrows and dumped into the trenches. The height from which the concrete is dumped, however, should not exceed 4 ft above the bottom of the trench, because when it falls from a greater height the heavy particles are apt to separate from the lighter ones. As soon as the concrete has been deposited in the trenches, it should be leveled off and then tamped with a wooden rammer weighing about 20 lb, until the water in the concrete is brought to the surface. Concrete should not be permitted to dry too quickly, and if twenty-four hours elapse between the deposits of the successive layers, the top of each layer should be sprinkled before the next is put in place. For buildings over five stories high, it is a good idea to place a stone footing course above the concrete footing, if suitable stones for the purpose can be obtained.

Brick Footings. Where the foundation walls are of brick, the footings are usually brick or concrete. For interior walls on dry ground, and in many

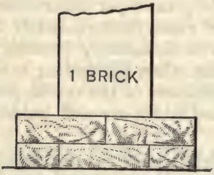

Fig. 3. Brick Footing. Wall One Brick Thick

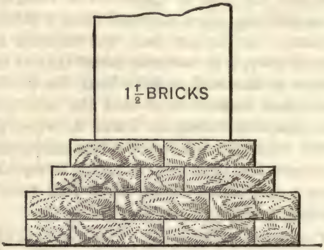

Fig. 4. Brick Footing. Wall One and One-half Bricks Thick

localities for outside walls, brick footings are fully as good as stone footings, provided good, hard bricks are used and the footings are properly built. Brick footings should always start with a DOUBLE COURSE on the foundation-bed and then be laid in single course for ordinary footings, the outside of the work being laid all HEADERS, as in the accompanying illustrations, and no course projecting more than one-fourth the length of a brick beyond the one above it, except in the case of an 8-in or 9-in wall. For brick footings under high or heavily loaded walls, each projecting course should be made double, the HEADER-COURSE above and the STRETCHER-COURSE below. Figs. 3, 4, 5 and 6 show footings for walls

varying from one brick to three bricks in thickness. The bricks used for footings should be the hardest and soundest that can be obtained, should be laid in cement mortar and should be either grouted or thoroughly slushed up, so that every joint shall be entirely filled with mortar. The writer favors GROUTING for brick footings, that is, the using of a thin mortar to fill the inside joints, as he has always found that it gives very satisfactory results. The bottom course of the footing should always be laid in a bed of mortar spread on the bottom of the trench after the latter has been carefully leveled. All bricks laid in warm or dry weather should be thoroughly wet before laying, for, if laid dry, they rob the mortar of a large percentage of the moisture it contains, greatly weakening the adhesion and strength of the mortar. Careful attention should be given to the laying of the footing courses of buildings, as upon them the stability of the work largely depends. If the bottom courses are not solidly bedded, if any rents or voids are left in the beds of the masonry, or if the materials themselves are unsound or badly put together, defects in the superstructure are almost sure to show themselves sooner or later, and almost always at a period when remedial efforts are difficult and expensive.

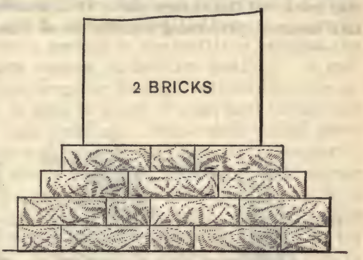

Fig. 5. Brick Footing. Wall Two Bricks Thick

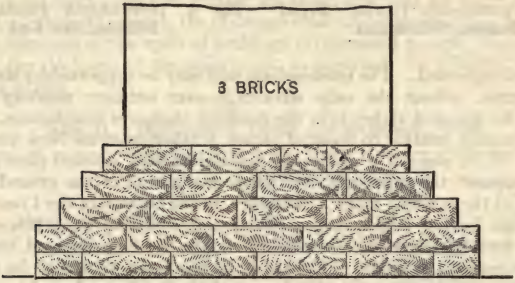

Fig. 6. Brick Footing. Wall Three Bricks Thick

Inverted Arches.* In a few buildings in which the external walls are divided into piers with wide openings between them, and in which the supporting power of the soil is not more than 2 or 3 tons per sq ft, it was thought desirable to connect the bases of the piers by means of INVERTED ARCHES, for the purpose of distributing the weight of the piers over the whole length of the footings. Examples of inverted-arch footings are shown in Figs. 7 † and 8,† which represent respectively the construction employed in the Drexel Building in Philadelphia

* For an example worked out in full, showing the method of proportioning inverted arches, see Chapter III, Building Construction and Superintendence, Part I, Masons' Work, by F. E. Kidder.

† From the Engineering Record, May, 1899, and Nov., 1890.

and the World Building in New York City. Unless the piers are about equally loaded, however, it is generally impossible to distribute the weight evenly, and if the arches extend to an angle of the building, the end-arch must be provided with ties of sufficient strength to resist the THRUST of the arch, as otherwise it may push out the corner-pier. It is usually better to build the piers with separate footings, projecting equally on all sides of the pier, and each proportioned

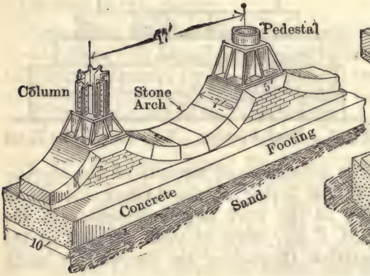

Fig. 7. Inverted-arch Footing. Drexel Building, Philadelphia

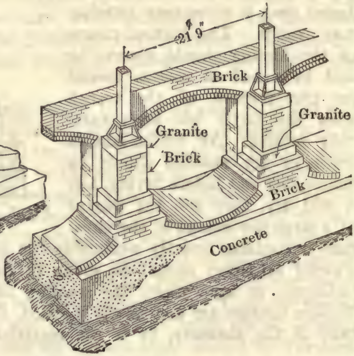

Fig. 8. Inverted-arch Footing. World Building, New York

to the load supported. The intermediate wall may be supported by steel beams or by arches. About the only advantage over ordinary masonry footings possessed by inverted arches is in the resulting shallower foundations.

The following, relating to inverted arches, is taken from the New York building law: "If, in place of a continuous foundation wall, isolated piers are to be built to support the superstructure, where the nature of the ground and the character of the building make it necessary, in the opinion of the Commissioner of Buildings having jurisdiction, inverted arches resting on a proper bed of concrete, both designed to transmit with safety the superimposed loads, shall be turned between the piers. The thrust of the outer piers shall be taken up by suitable wrought-iron or steel rods and plates." (Law of 1906.)

2. Cellar Walls and Basement Walls

Definitions. These terms are generally applied to walls which are below the surface of the ground or below the water-table or first-floor beams, which support the superstructure and which go down to the FOUNDATION WALLS, properly so called. (See Chapter II, Divisions 1 and 29.) Walls whose chief office is to withhold a bank of earth, such as the walls around areas, are called RETAINING-WALLS. (For retaining-walls, see Chapter IV.)

Materials for Cellar and Basement Walls. These walls may be built of brick, stone or concrete. BRICK is suitable only in very dry soils or for a party wall with a cellar or basement on each side of it. PORTLAND-CEMENT CONCRETE is an excellent material for foundation walls, and is being more extensively used in their construction every year. The concrete may be filled in between wooden forms, which hold it in place until it has set, or concrete blocks molded so as to form a solid wall may be used. If POURED CONCRETE is used the forms

should be removed as soon as the concrete has set and the walls should be sprinkled once or twice a day, if the weather is dry, so that the concrete will not dry too quickly Good hard LEDGE-STONE, especially if it comes from the quarry with flat beds, makes not only a strong wall but, if well built, one that will stand the effects of moisture and the pressure of the earth much better than a brick wall. Between a good stone wall and a wall of Portland-cement concrete, there is probably not much choice, except perhaps in the matter of expense, the relative cost of stonework and concrete varying in different localities. A wall built of soft stones, or stones that are very irregular in shape, with no flat surfaces, is greatly inferior to a concrete wall, or even to a wall of good hard bricks, and should be used only for dwellings or light buildings. Stone walls should never be less than 18 in thick, and should be well bonded, with full and three-quarter headers, and all spaces between the stones should be filled solid with mortar and broken stones or spalls. The MORTAR for stonework should be made of cement and sharp and rather coarse sand. The outside walls of cellars and basements should be PLASTERED smooth on the outside with 1 : 2, or 1 : 1½ cement mortar, from ½ to ¾ in thick. In heavy-clay soils it is a good idea to BATTER the walls on the outside, making them from 6 in to 1 ft thicker at the bottom than at the top.

Thickness of Cellar and Basement Walls. This is usually governed by that of the walls above, and also by the depth of the wall. Nearly all building regulations require that the thickness of the cellar and basement wall, to the depth of 12 ft below the grade-line, shall be 4 in greater than the thickness of the wall above for brick, and 8 in greater for stone, and that for every additional 10 ft or part thereof in depth, the thickness shall be increased 4 in. In all large cities the thickness of the walls of buildings is controlled by law. For buildings in which the thickness of the walls is not so governed, the following table will serve as a guide:

Table II. Thickness of Cellar and Basement Walls

Height of building	Dwellings, hotels, etc.		Warehouses	
	Brick, in	Stone, in	Brick, in	Stone, in
Two stories	12 or 16	20	16	20
Three stories	16	20	20	24
Four stories	20	24	24	28
Five stories	24	28	24	28
Six stories	28	32	28	32

3. Walls of the Superstructure

Brick and Stone Walls. Very little is known regarding the STABILITY of walls of buildings beyond what has been gained by practical experience. The only stresses in any horizontal sections of such walls, which can be determined with any accuracy, are the direct weight of the walls above and the pressure due to the floors and roof. In most walls, however, there is a tendency to BUCKLE, to overcome which it is necessary to make them thicker than would be required to resist the DIRECT CRUSHING STRESS. The resistance to fire should also be taken into account in deciding upon the thickness of any given wall.

The strength of a wall depends also very much upon the quality of the materials used and upon the way in which the wall is built. A wall bonded every 12 in in height, and with every joint slushed full with good rich mortar, is as strong as a poorly built wall 4 in thicker. Walls laid with cement mortar are also much stronger than those laid with lime mortar, and a brick wall built with bricks that have been well wet just before laying is very much stronger than one built with dry bricks.

Thickness of External Walls. In nearly all the larger cities of the country the minimum thickness of the walls is prescribed by law or ordinance, and as these requirements are generally ample they are commonly adhered to by architects when designing brick buildings. Table III * gives the thickness of brick walls required for MERCANTILE BUILDINGS in representative cities of different sections of the United States, and affords about as good a guide as one can have, because the values given, as a rule, represent the judgment of well-qualified and experienced persons. Walls for DWELLINGS are generally permitted to be 4 in less in thickness than for warehouses, although in some cities little or no distinction is made between business blocks and dwellings.

Table IV gives the thickness required for the brick walls of dwellings, tenements, hotels and office-buildings in Chicago. The thickness given is the minimum that should be allowed for the walls of such buildings. Most cities require 13-in walls for the upper story of three-story buildings and for large two-story dwellings. In St. Louis the two upper stories of dwellings are required to be 13 in, the next two below, 18 in, the next two 22 in, and the next two 26 in thick.

In compiling Table III the top of the second floor was taken at 19 ft above the sidewalk, and the height of the other stories at 13 ft 4 in, including the thickness of the floor, as the New York and Boston laws and the laws of some other cities give the height of the walls in feet instead of in stories. When the height of stories exceeds these measurements the thickness of the walls in some cases will have to be increased. The Chicago ordinance (1914) specifies that "where 12-in walls are used, the story-heights shall not exceed 18 ft, where 16-in walls are used, the story-heights shall not exceed 24 ft, and where 20-in walls are used, the story-heights shall not exceed 30 ft."

General Rule for Thickness of Walls. Although there are great differences in the thicknesses given in Table III, more indeed than there should be, a general rule might be formulated from it, for MERCANTILE BUILDINGS over four stories in height, which would be somewhat as follows:

For bricks equal to those used in Boston or Chicago, make the thickness of the three upper stories 16 in, of the next three below 20 in, the next three 24 in and the next three 28 in. For a poorer quality of material make only the two upper stories 16 in thick, the next three 20 in, and so on down. In buildings less than five stories in height the top story may be 12 in thick.

In determining the thickness of walls the following general principles should be recognized:

(1) That walls of warehouses and mercantile buildings should be heavier than those used for living or office purposes.

* Since this table was compiled, some provisions of some laws have been changed, but the requirements relating to the thicknesses of walls vary but little from those given. As building laws of different cities are amended from time to time, architects and builders must be guided by the code in force in the city in which a building is to be erected. The table represents the average requirements at the present time (1915) and is useful for comparative purposes and as a guide for those building outside of cities, or where no special building laws are in force.

Twelve-story	32	28	28	24	24	24	20	20	20	16	16	12	12

† These thicknesses are allowed when certain requirements are fulfilled in regard to lengths of walls, heights of stories, etc. For these modifying restrictions and for the classifications of buildings in regard to their uses the building laws must be consulted. The table is inserted in this form as a useful general guide and as an illustration of the average contemporary practice.

(2) That high stories and clear spans exceeding 25 ft require thicker walls.

(3) That the length of a wall is a source of weakness, and that the thickness should be increased 4 in for every 25 ft over 100 or 125 ft in length. In New York the thicknesses given in the table must be increased for buildings exceeding 105 ft in depth on the lot. In Western cities the tables are compiled fo warehouses 125 ft in depth, as that is the usual depth of lots in those cities.

(4) That walls containing over 33% of openings should be increased in thickness.

(5) That partition walls may be 4 in less in thickness than the outside walls if not over 60 ft long, but that no partition should be less than 8 in thick.

Walls Faced with Ashlar. "In reckoning the thickness of walls, ASHLAR shall not be included unless the walls are at least 16 in thick and the ashlar is at least 8 in thick, or unless alternate courses are at least 4 and 8 in to allow bonding with the backing. Ashlar shall be properly held by metal clamps to the backing or properly bonded to the same." *

Stone Walls should generally be 4 in thicker than required for brick walls.

Hollow Walls.† Hollow walls are undoubtedly desirable for dwellings, and might well be used for other buildings not more than four or five stories in height, on account of the security afforded from the weather. Owing to the fact that they are usually more expensive than solid walls and occupy more space, they are not very extensively used in this country.

The Boston building law requires that "vaulted walls shall contain, exclusive of withes, the same amount of material as is required for solid walls, and the masonry on the inside of the air-space in walls over two stories in height shall be not less than 8 in thick, and the parts on either side shall be securely tied together with ties not more than 2 ft apart in each direction."

Walls of Concrete Blocks. Blocks made of Portland-cement concrete, and formed in molds, are frequently used for building walls and partitions that are comparatively thin and bear light loads. Patents have been taken out on different forms of blocks and on machines or processes for making the same, and many buildings have been erected with walls built of these blocks. Most of the blocks are molded so as to form hollow walls. Block construction of this kind has an advantage over poured walls, in that the blocks are thoroughly seasoned before they are set and hence no provision is required for expansion or contraction. For the thin, light walls above mentioned the concrete-block construction is better adapted than solid concrete. The expense of forms is avoided and also the tendency to crack and to leave an unsatisfactory surface-finish. Concrete blocks may be substituted for any ordinary stone or brick masonry. Building laws usually require the thickness of walls of hollow concrete blocks to be not less than that required for brick walls. They should not be used in party walls. (See, also, Chapter XXIII, Subdivision 2.)

Walls of Hollow Tiles. Hollow tiles are used for the external walls of dwellings and sometimes for factories in some locations and under certain restrictions. For example, the building laws (1913) of the District of Columbia allow approved hollow tiles, not less than 12 in in thickness, to be used for the

* Boston Building Law, in force in 1915.

† For a full description of the details of construction of hollow, brick walls, see pages 367 to 375 of Building Construction and Superintendence, Part I, Masons' Work, by F. E. Kidder.

external walls of dwellings located not less than 3 ft from the side or party line of the lot. The Philadelphia laws do not allow the use of hollow tiles for any external wall or heavy bearing partition. As far as fire-resistance is concerned, construction of hollow tiles is, of course, superior to wooden construction, and its use is increasing, the outside walls being usually covered with cement or stucco, although occasionally left with the finished texture of the tile surface. The reason hollow tiles are prohibited by building ordinances for certain uses is because when heated and then suddenly cooled by water they are apt to crack from the sudden contraction. Recent conflagrations have shown that hard-burned terra-cotta will crack and fall to pieces under severe heat alone. (See, also, Chapter XXIII, Subdivision 2.)

Party Walls. There is much diversity in building regulations regarding the thickness of party walls, although they all agree in that such walls should never be less than 12 in thick. About one-half of the laws require that party walls shall be of the same thickness as external walls; the remainder are about equally divided between making the party walls 4 in thicker or thinner than for independent side walls. When the walls are proportioned by the rule previously given the author believes that the thickness of the party walls should be increased 4 in in each story. The floor-load on party walls is obviously twice that on side walls, and the necessity for thorough fire-protection is greater in the case of party walls than in other walls.

Enclosing Walls for Steel, Skeleton Construction. In buildings of the skeleton type the outer masonry walls are usually supported either in every story or every other story by the steel framework, and carry nothing but their own weight. Such walls may, therefore, be considered as only one or two stories high, and are usually made only 12 in thick for the whole height of a twelve-story or fifteen-story building. For SKELETON CONSTRUCTION, the Chicago ordinance allows ENCLOSING WALLS of 12-in thickness for all stories. The New York City building law requires the use of 12-in enclosing walls for 75 ft of the uppermost height thereof, or to the nearest tier of beams to that measurement, and 4 in additional thickness for every lower 60-ft section or to the nearest tier of beams to such vertical measurement, down to the tier of beams nearest to the curb-level. But, on account of the severity of some of the requirements as applied to very high buildings of skeleton construction, permission is frequently given by the Commissioners of Buildings, who are empowered to modify the building laws within certain limits, to reduce the thicknesses of curtain walls for very high buildings, according to the peculiar circumstances of each case, without endangering the strength and safety of the building.* A few of the earlier tall buildings were built with SELF-SUSTAINING WALLS, starting from the foundation, while columns were introduced merely to support the floors and to give additional stiffness. "The World Building, New York City, erected in 1890, is an extreme example of high-building construction, with self-sustaining walls. The main roof is 191 ft above the street-level, making thirteen main stories, above which is a dome containing six stories, in all, a height of 275 ft above the street. The self-sustaining walls are built of sandstone, brick and terra-cotta, the thickness increasing from 2 ft at the top to as much as 11 ft 4 in near the bottom, where the walls are offset to a concrete footing 15 ft wide. The walls are vertical on the outside faces, the thickness being varied by inside offsets, so that the columns are recessed into the walls at the bottom, but emerge and are some distance clear of the walls at the top."†

* The revised Code, 1916–17, allows 12-in curtain walls in skeleton buildings the entire height of building, when supported on girders in each story.

† From Architectural Engineering, by J. K. Freitag.

4. Natural Cements *

Properties and Uses of Natural Cements. The first hydraulic cements used in this country were NATURAL CEMENTS, manufactured by the calcination of argillaceous limestone containing sufficient silica, alumina and iron oxide to confer hydraulic properties when the burned rock was pulverized and gauged with water. These natural cements were very widely manufactured and used until recent years, when they have been practically completely replaced by Portland cement. Natural cements vary in color from light yellow to dark brown according to the content of oxide of iron, and in distinction to Portland cements they are not uniform in their composition or behavior. The chemical composition and physical characteristics of various natural cements vary within wide limits, not only between cements manufactured in different mills, but between the products of the same mill at different times. Natural cements set more rapidly than Portland cements and are slower in developing strength. The production of natural cement in the United States for 1913 was 800 000 barrels, while during the same year the production of Portland cement was 82 000 000 barrels; from which it is seen that the natural-cement industry is relatively almost extinct. Natural cement may be used in massive masonry where weight rather than strength is the essential feature. It is used, also, for certain special purposes, such as in the manufacture of safes and in certain industries where a quick-setting cement is necessary. Where economy is the governing factor, a comparison may be made between the use of natural cement and a leaner mixture of Portland cement that will develop the same strength.

Weight. The specifications of the American Society for Testing Materials require that a bag of natural cement shall contain 94 lb, net, of cement, and that each barrel of natural cement shall contain three bags of this NET WEIGHT.

Strength. A natural-cement mortar, in order to comply with the requirements of the standard specifications of the American Society for Testing Materials, must show a TENSILE STRENGTH, for the neat cement, of at least 150 lb per sq in, when one week old, and 250 lb at the end of 28 days; or, when mixed with three parts of standard Ottawa sand, 50 lb at the end of one week, and 125 lb at the end of 28 days. The strength of 1 : 2 natural-cement mortar is about equal to that of 1 : 4 Portland-cement mortar.

Proportions of Natural Cement and Sand for Mortar and Concrete. For mortar for rubble-stone masonwork and ordinary brickwork, one part of natural cement may be mixed with three parts of sand, by measure.

Hydraulic Lime. A product closely related to natural cement is HYDRAULIC LIME. This is manufactured in the same way as natural cement, but the rock used contains sufficient lime to permit it to slake like quicklime. When the resulting product is pulverized, it sets and hardens as an hydraulic cement. Hydraulic limes are largely manufactured in Europe, and especially in France and Belgium, but in the United States they have been manufactured only in a few localities. This is due to the fact that while rock of suitable composition is widely found, the impurities are not uniformly distributed through it, but are found in layers or seams which prevent the material from being uniformly burned. The portion of the rock immediately adjacent to and including the seam of impurities overburns, frequently melting like a slag, while the purer portions consist simply of quicklime; and while the resulting mass slakes partly, the product when pulverized is unreliable as a cement.

* Practical data relating to Cements, Limes and Plasters were furnished the Editor by the Charles Warner Company of Wilmington, Del. For Limes and Plasters, see Part III, pages 1462 to 1472.

Grappier Cement is a BY-PRODUCT produced during the calcination of HYDRAULIC LIME.

La Farge Cement is an imported NON-STAINING GRAPPIER CEMENT. It develops nearly the same strength as the Portland cements.

5. Artificial Cements

The Artificial Cements used in the United States include Portland cement and Puzzolan or slag cement.

Portland Cement. The principal artificial cement in this country to-day is PORTLAND CEMENT. It is manufactured from two raw materials which are ground to extreme fineness to secure an intimate mix before burning, and it is from this fact that it derives its name, ARTIFICIAL CEMENT. These materials must be so proportioned that in the finished cement, silica, alumina, iron oxide and lime will be present in a certain ratio which must be maintained within close limits. In the Lehigh Valley region of Pennsylvania, in which are located some of the leading Portland-cement mills of the United States, the raw materials used are limestone and cement-rock. The cement-rock is an impure limestone carrying argillaceous or clay-matter. In order to bring the lime-content up to the required percentage, it is usually found necessary in this region to add limestone. In other districts the raw materials used are limestone and clay, limestone and shale, marl and clay and also blast-furnace slag and limestone. The product from the last-mentioned mixture should not be confused with the common slag cement or Puzzolan cement, as the slag is simply used as a raw material supplying silica, alumina, iron oxide and lime; and with the exception of the use of slag to furnish these ingredients, the process of manufacture and the properties are substantially the same as for the other Portland cements. The raw mix in a Portland cement mill is analyzed at most mills several times each hour to keep the composition of the cement within the proper limits. The raw material, which is pulverized as fine as the finished cement, is burned in rotary kilns, the fuel used in most instances being powdered coal. From the kiln it issues in the form of CLINKER, the name given to the semivitrified product. After cooling, calcium sulphate in the form of gypsum is added to control the set and the product is pulverized and packed for shipment. The manufacture and properties of Portland cement have been made the subject of careful study by the American Society for Testing Materials and by the American Society of Civil Engineers. The result of this study is embodied in the standard specifications of the American Society for Testing Materials, extracts from which are given in the paragraphs following. These specifications furnish a reliable guide for the acceptance or rejection of any shipment of cement and have been very widely adopted by the leading architects and engineers of this country. These specifications do not stipulate that Portland cement shall consist of any one particular composition, but in this respect confine themselves to the limitation of the magnesia (MgO) and anhydrous sulphuric acid (SO_3) content. The reason for this is that with different raw materials it is found necessary to vary the composition of the cement to obtain the correct physical properties in the finished material. Different cements which satisfy the requirements of these standard specifications are generally considered satisfactory cements for use, although the composition of one may vary in some particulars from that of another. The CHEMICAL COMPOSITION of a good brand of Portland cement is about as follows: Lime, 62; silica, 23; alumina, 8; and impurities, such as iron oxide, magnesia, and sulphuric acid, 7.

Standard Specifications for Portland Cement.* The following extracts give the most important requirements for Portland cement:

Definition. This term is applied to the finely pulverized product resulting from the calcination to incipient fusion of an intimate mixture of properly proportioned argillaceous and calcareous materials, and to which no addition greater than 3% has been made subsequent to calcination.

Specific Gravity. The specific gravity of cement shall be not less than 3.10. Should the test of cement as received fall below this requirement, a second test may be made upon a sample ignited at low red heat. The loss in weight of the ignited cement shall not exceed 4%.

Fineness. It shall leave by weight a residue of not more than 8% on the No. 100, and not more than 25% on the No. 200 sieve.

Time of Setting. It shall not develop initial set in less than 30 minutes, and must develop hard set in not less than 1 hour, nor more than 10 hours.

Tensile Strength. The minimum requirements for tensile strength for briquettes 1 sq in in cross-section shall be as follows, and the cement shall show no retrogression in strength within the periods specified:

Neat Cement

Age	Strength
24 hours in moist air	175 lb per sq in
7 days (1 day in moist air, 6 days in water)	500 lb per sq in
28 days (1 day in moist air, 27 days in water)	600 lb per sq in

One Part Cement, Three Parts Standard Ottawa Sand

7 days (1 day in moist air, 6 days in water)	200 lb per sq in
28 days (1 day in moist air, 27 days in water)	275 lb per sq in

Constancy of Volume. Pats of neat cement about 3 in in diameter, ½ in in thickness at the center, and tapering to a thin edge, shall be kept in moist air for a period of 24 hours.

(1) A pat is then kept in air at normal temperature and observed at intervals for at least 28 days.

(2) Another pat is kept in water maintained as near 70° F. as practicable, and observed at intervals for at least 28 days.

(3) A third pat is exposed in any convenient way in an atmosphere of steam, above boiling water, in a loosely closed vessel for 5 hours.

These pats, to satisfactorily pass the requirements, shall remain firm and hard and show no signs of distortion, checking, cracking, or disintegrating.

Sulphuric Acid and Magnesia. The cement shall not contain more than 1.75% of anhydrous sulphuric acid (SO_3), nor more than 4% of magnesia (MgO).

Puzzolan or Slag Cements are not used extensively and never in important work. Their manufacture and properties may be briefly described as follows: Blast-furnace basic slag is granulated by running it in a molten condition into water. This accomplishes two objects. The slag is broken up into fine particles and the sudden chilling enhances its hydraulic properties. These particles are dried and ground with hydrated lime, in the proportion of from 15 to 25% of hydrated lime and from 75 to 85% of granulated slag. Such cement, known as slag cement, is slow-setting and slow-hardening, and does not develop as

* From the Standard Specifications for Cement adopted August 16, 1909, by the American Society for Testing Materials. See, also, Chapter XXIV, page 912, where, in a footnote, reference is made to a Report of changes in the standard specifications for Portland cement, made by a special Joint Committee and adopted by the A. S. T. M. in 1916.

much strength as natural or Portland cement. Slag cements are characterized by their light lilac color, their extreme fineness and their low specific gravity. They are considered unreliable for use except for foundation-work under ground where they are not exposed to air or running water.

Stainless Cements. Any ordinary Portland or natural cement will stain limestones, some porous marbles, some granites and some other light-colored stones. The best non-staining material is lime, that is, lime free from excess of iron oxide. There are some Portland cements, however, which are called NON-STAINING CEMENTS, and where care is used in their manufacture and they are free or comparatively free from iron oxide, they cause no trouble. Among the non-staining cements which have been extensively used for masonry on which staining would be objectionable, is La Farge Cement, before mentioned. It is made at Teil, France, is light-colored and contains a small percentage of iron and soluble salts. There are other non-staining cements on the market. For setting stones, and in order to RETARD THE SETTING of the cement until the stones are well bedded, 1 part by volume of lime-paste is usually mixed with 4 parts of the cement.

Cost of Portland Cement. Portland cement can now (1915) be purchased in this country at prices ranging from 90 cents to $2.50 per barrel, free on board cars at the mills. The cost of the sacks and the freight are extra. The retail price for single barrels varies from about $2.00 to $2.50 per barrel. As a rule, the cost of cement in carload lots is about 85 cts per bbl at the mills. An extra charge of 10 cts per bbl for bags is made when the cement is delivered in paper bags. The extra charge is 40 cts, if delivered in cloth, but the mills refund this 40 cts when the bags are returned in good condition. There is a charge of 40 cts when the cement is furnished in wooden barrels and no allowance is made for barrels returned. It is generally cheaper in the end to buy the cement in cloth bags and return the empty bags. For about 500 miles, the freight-charges are about 40 cts per bbl of cement, making the total cost per bbl for this distance $1.25, when purchased in cloth bags and when the 40 cts per bag are refunded. Testing costs from 3 to 5 cts per bbl, or from $5 to $6 per carload. Unloading and storing near the station cost about 3 cts per bbl, and about 2 cts per bbl are usually added to the costs to allow for handling and returning empty sacks, and freight-charges for and damage to same. Teaming costs about 5 cts per bbl per mile. The total cost, therefore, according to these average costs, is about $1.38 per bbl for the cement ready for use for mortar or concrete. (For Cost of Concrete, see page 249.)

Water Required in Mixing Cement Mortar. Good Portland cement requires relatively little water to make a good mortar. Neat cement will take from 20 to 22% (by weight) of water to produce the normal consistency, a quick-setting cement requiring more water than one that is slow-setting. If a greater quantity of water is required, it indicates the presence of an excess of free lime. When sand is mixed with cement, in the proportion of 3 to 1, not more than from 9 to 12½% (by weight) of water will be required. Natural cements and slag cements require more water than do Portland cements. Too much water drowns the cement, retards the setting and weakens the mortar. Cements can also be weakened or even spoiled by a deficiency of water.

Portland-Cement Mortar. For first-class mortar not more than 3 bbl of sand should be added to 1 bbl of cement. For rubble stonework under ordinary conditions a mortar composed of 4 parts of sand to 1 of cement will answer every purpose, and be much stronger than lime mortar. For the top surface of floors and walks, from 1 to 1½ parts of sand may be mixed with 1 part of cement.

1 to 3 Portland-cement mortar has about the same strength at the end of one year as 1 to 1 natural-cement mortar. Mortar made with fine sand requires a much larger quantity of cement to obtain a given strength than mortar made with coarse sand.

Effects of Low Temperatures and Freezing on Cement Mortars. The rate of setting and hardening of cement mortar is greatly affected by the temperature, and the exposure and loading of new work often depends upon the prevailing temperature. The freezing of natural-cement mortars should be entirely avoided as it seriously injures them. Although freezing greatly retards the hardening of Portland-cement mortars and concretes, it does not appear to injure them. Thin coats of mortar, such as plaster, and troweled surfaces or those on which free moisture is formed should not be applied in freezing weather as they are apt to scale. In general, it is undesirable to work with mortar or concrete in freezing weather, as the difficulties of properly mixing and placing the materials are then increased; it must be admitted, however, that successful work with Portland-cement mortar and concrete has been done in temperatures considerably below freezing.

The Effect of Salt in Mortar. When salt is added to the water of mixture, the freezing-point is lowered, and, within certain limits, the freezing of the mortar or concrete is prevented. The ultimate strength of mortar does not appear to be reduced when the amount of salt does not exceed 10%. Tetmajer gives the amount of salt required to lower the freezing-temperature as equal to 1% of the weight of the water per degree F. below 32°. The rule for the proportion of salt used in the works at Woolwich Arsenal, is said to have been as follows: "Dissolve 1 lb of rock-salt in 18 gal of water when the temperature is at 32° F., and add 3 oz of salt for every three degrees of lower temperature."

Effect of Hot Water and of Soda. Hot water hastens the setting of Portland-cement mortar, and 2 lb of carbonate of soda in 1 gal of water, boiled and mixed in mortar, hastens the setting and lessens the danger of freezing.

Quantity of Mortar required for Masonry and Plastering.* "One bbl of Portland cement and 3 bbl of sand, thoroughly and properly mixed, will make 3⅓ bbl, or 12 cu ft of good strong mortar. This will be sufficient to lay up 1½ cu yd of rough stone, or about 750 bricks, with from ¼ to ⅜-in joints, or cover 125 sq ft of surface, 1 in thick, or 250 sq ft, ½ in thick."

"One bbl of natural cement and 2 bbl of lime, mixed with about ½ bbl of water, will make 8 cu ft of mortar, sufficient to lay 522 common bricks, with from ¼ to ⅜-in joints, or about 1 cu yd of rough rubble."

For the top coat of walks or floors, 1 bbl of Portland cement and 1 of sand will cover from 75 to 80 sq ft, ½ in thick, or from 50 to 56 sq ft ¾ in thick.

One bbl of Portland cement and 1½ bbl of sand will cover from 110 to 120 sq ft of floor, ½ in thick, or from 75 to 80 sq ft, ¾ in thick.

The Mixing of Mortar. Mortar may be mixed by hand or by mechanical mixers, the latter being preferable for the mixing of large quantities. When the mixing is by hand, it should be done on platforms made water-tight to prevent the loss of cement. The cement and sand should be mixed dry in small batches and in the proportions required, the platform being clean. Water is added and the whole mass remixed until it is homogeneous and leaves the mixing hoe clean when drawn out. Mortar should never be retempered after it has begun to set.

* These figures can be considered as approximate only, as the amount of mortar will vary on different jobs.

Adhesive Strength of Portland Cement, Sulphur and Lead for Anchoring Bolts.* "Fourteen holes were drilled in a ledge of solid limestone, seven of them being 1⅜ and seven 1⅝ in in diameter, and all being 3½ ft deep. Seven ¾ and seven 1-in bolts were prepared with thread and nut on one end and with the other end plain but ragged for a length of 3½ ft.

"Four were anchored with sulphur, four with lead and six with cement, mixed neat. Half the number of the ¾-in and 1-in bolts being thus anchored with each of the three materials, all stood until the cement was two weeks old. Then a lever was rigged and the bolts pulled, with the following results.

"Sulphur: Three bolts out of four developed their full strength 16 000 and 31 000 lb. One 1-in bolt failed by drawing out, under 12 000 lb. Lead: Three bolts out of four developed their full strength, as above. One 1-in bolt pulled out, under 13 000 lb. Cement: Five of the bolts out of six broke without pulling out. One 1-in bolt began to yield in the cement at 26 000 lb, but sustained the load a few seconds before it broke.

"While this experiment demonstrated the superiority of cement, both as to strength and ease of application, it did not give the strength per square inch of area. To determine this, four specimens of limestone were prepared, each 10 in wide, 18 in long and 12 in thick, two of them having 1¾-in holes, and two of them 2¾-in holes drilled in them. Into the small holes 1-in bolts were cemented, one of them being perfectly plain round iron, and the other having a thread cut on the portion which was embedded in the cement. Into the 2¾-in holes were cemented 2-in bolts similarly treated, and the four specimens were allowed to stand 13 days before completing the experiment. At the end of this time they were put into a standard testing-machine and pulled. The plain 1-in bolt began to yield at 20 000 lb and the threaded one at 21 000 lb. The 2-in plain bolt began to yield at 34 000 lb and the threaded one at 32 000 lb, the force in all cases being very slowly applied. The pump was then run at a greater speed, and the stones holding the 2-in bolts split at 67 000 lb in the case of the smooth one and at 50 000 lb in the case of the threaded one.

"It is thus seen that for anchoring bolts in stone, cement is more reliable, stronger and easier of application than either lead or sulphur, and that its resistance is from 400 to 500 lb per sq in of surface exposed. It is also a well-ascertained fact that it preserves iron rather than corrodes it. The cement used throughout the experiment was an English Portland cement."

6. Concrete †

Properties and Uses of Concrete.‡ There is probably no material that is so enduring or better adapted for foundations, walks and basement floors, etc., than cement concrete, and for certain classes of buildings it is used with advantage for the walls, floors and interior supports. There are now thousands of buildings in this and other countries in which all of the structural portions are formed of reinforced concrete, and the use of Portland-cement concrete for a

* The test of these materials is reported in the American Architect, page 105, vol. xxiv.

† The subject of concrete in general, including plain or mass-concrete and reinforced concrete, is to-day so important, and the available data so vast in amount that only those brief statements of general principles and of the best engineering practice that are the most important for the architect and builder to know can be included in a handbook of this kind. For full treatments of the subject, the readers are referred to the numerous recent treatises, tests, proceedings of engineering societies, etc.

‡ For reinforced Concrete, see Chapter XXIV; for Concrete Foundations, Chapter II; for Reinforced-Concrete Factory Construction, Chapter XXV; and for Strength of Concrete, Chapter V. See, also, Chapter XXIII, pages 817 and 844.

great variety of purposes is rapidly extending, due to the reduced price of Portland cement, and to a better appreciation and understanding of its properties and merits. Concrete may be defined as an artificial stone, made by uniting cement, water and what is called an aggregate, consisting of small and large particles of sand or screenings and gravel or broken stone; and when made with good Portland cement, in proper proportions, it becomes so hard and strong that when pieces of it are broken, the line of fracture often passes through the particles of stone, showing that the adhesion of the cement to the stone is greater than the cohesive strength of the stone itself.

The Aggregates.* "Extreme care should be exercised in selecting the aggregates for mortar and concrete, and careful tests made of the materials for the purpose of determining their qualities and the grading necessary to secure maximum density or a minimum percentage of voids. A convenient coefficient of density is the ratio of the sum of the volumes of materials contained in a unit volume to the total unit volume. (See, also, page 914.)

"(1) **Fine Aggregates** should consist of sand, crushed stone, or gravel screenings, graded from fine to coarse and passing when dry a screen having ¼-in diam holes; it preferably should be of siliceous material, and should be clean, coarse, free from dust, soft particles, vegetable loam or other deleterious matter, and not more than 6% should pass a sieve having 100 meshes per lin in. Fine aggregates should always be tested. Fine aggregates should be of such quality that mortar composed of one part Portland cement and three parts fine aggregate by weight when made into briquettes will show a tensile strength at least equal to the strength of 1 : 3 mortar of the same consistency made with the same cement and standard Ottawa sand. This is a natural sand obtained at Ottawa, Ill., passing a screen having 20 meshes and retained on a screen having 30 meshes per lin in. It is prepared and furnished by the Ottawa Silica Company, for 2 cts per lb, free on board cars, at Ottawa, Ill., under the direction of the Special Committee on Uniform Tests of Cement of the American Society of Civil Engineers. If the aggregate be of poorer quality the proportion of cement should be increased in the mortar to secure the desired strength. If the strength developed by the aggregate in the 1 : 3 mortar is less than 70% of the strength of the Ottawa-sand mortar, the material should be rejected. To avoid the removal of any coating on the grains, which may affect the strength, bank sands should not be dried before being made into mortar, but should contain natural moisture. The percentage of moisture may be determined upon a separate sample for correcting weight. From 10 to 40% more water may be required in mixing bank or artificial sands than for standard Ottawa sand to produce the same consistency.

"(2) **Coarse Aggregates** should consist of crushed stone or gravel which is retained on a screen having ¼-in diam holes and graded from the smallest to the largest particles; they should be clean, hard, durable and free from all deleterious matter. Aggregates containing dust and soft, flat or elongated particles should be excluded from important structures."

Any kind of stone is suitable for the coarse aggregate which has such strength that the strength of the concrete is not limited by the strength of the stone. Great strength is of little advantage beyond this minimum. The stones generally employed are granites, traps and limestones. Shales and sandstones of

* Most of the matter of this paragraph, and of following paragraphs relating to concrete, consists of data and conclusions formulated by the joint committees of the Am. Soc. C. E., Am. Soc. for Test. Mats., Am. Ry. Eng. and Maint. of Way Asso., and Asso. of Am. Portland Cement Manfrs. In regard to Aggregates, etc., see, also, the same subjects in Chapter XXIV, pages 913 and 914, and foot-notes on page 913 in that chapter.

deficient strength should be tested before use. Screened gravel generally makes a good coarse aggregate. "The maximum size of the coarse aggregate is governed by the character of the construction. For reinforced concrete and for small masses of unreinforced concrete, the aggregate must be small enough to produce with the mortar a homogeneous concrete of viscous consistency which will pass readily between and easily surround the reinforcement and fill all parts of the forms. For concrete in large masses the size of the coarse aggregate may be increased, as a large aggregate produces a stronger concrete than a fine one, although it should be noted that the danger of separation from the mortar becomes greater as the size of the coarse aggregate increases."

The use to be made of the concrete determines the maximum size of the coarse aggregate. When used in mass-concrete construction, such as heavy walls, the maximum size may run up to 2½ and 3 in with good results. For reinforced work and thin walls, however, it is necessary to reduce the maximum size to 1 in or less. It has been found that the following are the maximum sizes for the coarse aggregate of plain or mass-concrete in the best practice: for foundations, 2½ in; for abutments, 2 in; for arch-rings, 1¼ in; and for copings, thin walls, etc., 1 in.

"Cinder concrete should not be used for reinforced-concrete structures. It may be allowable in mass for very light loads or for fire-protection purposes. The cinders used should be composed of hard, clean, vitreous clinkers, free from sulphides, unburned coal, or ashes. (See, also, page 914.)

"**Water for Mixing Concrete.** The water used in mixing concrete should be free from oil, acid, alkalies, or organic matter."

Preparing and Placing Mortar and Concrete. "(1) **Proportions.*** The materials to be used in concrete should be carefully selected, of uniform quality, and proportioned with a view to securing as nearly as possible a maximum density.

"(a) Unit of Measure. The unit of measure should be the cubic foot. A bag of cement, containing 94 lb, net, should be considered the equivalent of 1 cu ft. The measurement of the fine and coarse aggregates should be by loose volume.

"(b) Relation of Fine and Coarse Aggregates. The fine and coarse aggregates should be used in such relative proportions as will insure maximum density. In unimportant work it is sufficient to do this by individual judgment, using correspondingly higher proportions of cement; for important work these proportions should be carefully determined by density-experiments and the sizing of the fine and coarse aggregates should be uniformly maintained or the proportions changed to meet the varying sizes.

"(c) Relation of Cement and Aggregates. For reinforced-concrete construction, one part of cement to a total of six parts of fine and coarse aggregates, measured separately, should generally be used. For columns, richer mixtures are generally preferable, and in massive masonry or rubble concrete a mixture of 1 : 9 or even 1 : 12 may be used. These proportions should be determined by the strength or the wearing-qualities required in the construction at the critical period of its use. Experienced judgment based on individual observation and tests of similar conditions in similar localities is an excellent guide as to the proper proportions for any particular case. For all important construction, advance tests should be made of concrete, of the materials, proportions and consistency to be used in the work. These tests should be made under laboratory conditions to obtain uniformity in mixing, proportioning and

* See, also, in Chapter XXIV, paragraphs relating to these subjects on page 915, and foot-note relating to the same, on page 913 of that chapter.

storage, and in case the results do not conform to the requirements of the work, aggregates of a better quality should be chosen or richer proportions used to obtain the desired results."

Professor Turneaure of the University of Wisconsin gives the following as the proportions of cement, sand and coarse aggregate generally used for various classes of work:

For reinforced columns and structural parts requiring extra strength	from 1 : 1 : 2 to 1 : 1½ : 3
For buildings, thin walls, reinforced concrete, tanks and impervious construction	from 1 : 2 : 4 to 1 : 2½ : 4½
For structures requiring great strength rather than mass	from 1 : 2½ : 5 to 1 : 3 : 6
For structures requiring mass rather than strength, foundations, etc..................	from 1 : 3 : 6 to 1 : 4 : 8

"(2) **Mixing Concrete.** The ingredients of concrete should be thoroughly mixed and the mixing should continue until the cement is uniformly distributed and the mass is uniform in color and homogeneous. As the maximum density and greatest strength of a given mixture depend largely on thorough and complete mixing, it is essential that the work of mixing should receive special attention and care. Inasmuch as it is difficult to determine, by visual inspection, whether the concrete is uniformly mixed, especially where limestone or aggregates having the color of cement are used, it is essential that the mixing should occupy a definite period of time. The minimum time will depend on whether the mixing is done by machine or hand.

"(a) Measuring Ingredients. Methods of measurement of the proportions of the various ingredients should be used which will secure separate and uniform measurements of cement, fine aggregate, coarse aggregate and water at all times.

"(b) Machine-Mixing. When the conditions will permit, a machine-mixer of a type which insures the uniform proportioning of the materials throughout the mass should be used, as a more uniform consistency can be thus obtained. The mixing should continue for a minimum time of at least one minute after all the ingredients are assembled in the mixer.

"(c) Hand-Mixing. When it is necessary to mix by hand, the mixing should be on a water-tight platform and especial precautions should be taken to turn all the ingredients together at least six times and until they are homogeneous in appearance and color."

The most satisfactory method * of mixing concrete by hand is to first prepare for the mixing of the materials, a tight floor of planks, or, better still, of sheet iron with the edges turned up about 2 in. Upon this platform should first be spread the sand, and upon this the cement. The two should then be thoroughly and immediately mixed by means of shovels or hoes until of an even color. Enough water should be added to make a thin mortar which is then spread again. The gravel, if used, should then be added, and then the broken stone. Gravel and stone should be first thoroughly wet, if originally dry. The mass should be turned until all the ingredients are thoroughly incorporated and all the stone and gravel covered with mortar, this requiring from four to six turnings.

"(d) Consistency. The materials should be mixed wet enough to result in a concrete of such a consistency that it will flow into the forms and about the metal reinforcement when used, and which, at the same time, can be conveyed from

* This paragraph is condensed from several recent specifications.

the mixer to the forms without separation of the coarse aggregate from the mortar.

"(e) Retempering. Mortar or concrete should not be remixed with water after it has partly set."

(3) **Placing Concrete.** "(a) Methods. Concrete after the completion of the mixing should be handled rapidly, and in as small masses as is practicable, from the place of mixing to the place of final deposit, and under no circumstances should concrete be used that has partly set. A slow-setting cement should be used when a long time is likely to occur between mixing and placing. Concrete should be deposited in such a manner as will permit the most thorough compacting, such as can be obtained by working with a straight shovel or slicing tool kept moving up and down until all the ingredients have settled in their proper places by gravity and the surplus water has been forced to the surface. Special care should be exercised to prevent the formation of LAITANCE,* which hardens very slowly and forms a poor surface on which to deposit fresh concrete. All LAITANCE should be removed. When suspended work is resumed, concrete previously placed should be roughened, thoroughly cleansed of foreign material and laitance, thoroughly wetted and then slushed with a mortar consisting of one part Portland cement and not more than two parts fine aggregate. The faces of concrete exposed to premature drying should be kept wet for a period of at least seven days."

"(b) Mixing and Depositing Concrete in Freezing Weather. Concrete should not be mixed or deposited at a freezing temperature, unless special precautions are taken to avoid the use of materials covered with ice-crystals or containing frost, and to provide means to prevent the concrete from freezing after being placed in position and until it has thoroughly hardened. As the coarse aggregate forms the greater portion of the concrete, it is particularly important that this material be heated to well above the freezing-point.

"(c) Rubble Concrete. Where the concrete is to be deposited in massive work, its value may be improved and its cost materially reduced by the use of clean stones thoroughly embedded in the concrete and as near together as is possible while still entirely surrounded by concrete.

"(d) Depositing Concrete Under Water. In placing concrete under water it is essential to maintain still water at the place of deposit. The use of TREMIES,† properly designed and operated, is a satisfactory method of placing concrete through water. The concrete should be mixed very wet (more so than is ordinarily permissible) so that it will flow readily through the tremies and into the places with practically a level surface. The coarse aggregate should be smaller than ordinarily used, and never more than 1 in in diameter. The use of gravel facilitates mixing and assists the flow of concrete through the tremies. The mouth of the tremie should be buried in the concrete so that it is at all times entirely sealed and the surrounding water prevented from forcing itself into the tremie; the concrete will then discharge without coming in contact with the water. The tremie should be suspended so that it can be lowered quickly when it is necessary either to choke off or prevent a too rapid flow; the

* Laitance is a whitish, gelatinous substance of about the same composition as cement but with little tendency to harden. It accompanies a disintegration of some of the cement from the surface of concrete which is exposed to the action of water in which it is deposited. The concrete is thus weakened and the laitance, also, weakens the bond between old and new material and should be removed before fresh concrete is placed.

† A tremie is a round or square box or tube of wood or plate iron open at the top and bottom. The diameter varies from 12 to 24 in. The tremie rests in the deposited concrete, extends above the water-level and is kept full of concrete, which escapes at the bottom as the tube is shifted over the surface.

lateral flow should preferably be not over 15 ft. The flow should be continuous in order to produce a monolithic mass and to prevent the formation of laitance in the interior. In large structures it may be necessary to divide the mass of concrete into several small compartments or units, filling one at a time. With proper care it is possible in this manner to obtain as good results under water as in the air."

Forms for Concrete. "Forms should be substantial and unyielding, so that the concrete will conform to the designed dimensions and contours, and should be tight in order to prevent the leakage of mortar. The time for removal of forms is one of the most important considerations in the erection of a structure of concrete or reinforced concrete. Care should be taken to inspect the concrete and ascertain its hardness before removing the forms. So many conditions affect the hardening of concrete, that the proper time for the removal of the forms should be decided by some competent and responsible person, especially where the atmospheric conditions are unfavorable. It may be stated, in a general way, that forms should remain in place longer for reinforced concrete than for plain or massive concrete, and that the forms for floors, beams and similar horizontal structures should remain in place much longer than for vertical walls. When the concrete gives a distinctive ring under the blow of a hammer, it is generally an indication that it has hardened sufficiently to permit the removal of the forms with safety. If, however, the temperature is such that there is any possibility that the concrete is frozen, this test is not a safe reliance, as frozen concrete may appear to be very hard."

Shrinkage of Concrete and Temperature-Changes. "Shrinkage of concrete, due to hardening and contraction from temperature-changes, causes cracks, the size of which depends on the extent of the mass. The resulting stresses are important in monolithic construction and should be considered carefully by the designer; they cannot be counteracted successfully, but the effects can be minimized. Large cracks produced by quick hardening or wide ranges of temperature can be broken up to some extent into small cracks by placing reinforcement in the concrete; in long continuous lengths of concrete, it is better to provide shrinkage-joints at points in the structure where they will do little or no harm. Reinforcement is of assistance and permits longer distances between shrinkage-joints than when no reinforcement is used. Small masses or thin bodies of concrete should not be joined to larger or thicker masses without providing for shrinkage at such points. Fillets similar to those used in metal castings, but of larger dimensions, for gradually reducing from the thicker to the thinner body, are of advantage. Shrinkage-cracks are likely to occur at points where fresh concrete is joined to that which is set, and hence in placing the concrete, construction-joints should be made on horizontal and vertical lines, and, if possible, at points where joints would naturally occur in dimension-stone masonry."

Effect of Heat on Concrete Fireproofing.* "The actual fire-tests of concrete and reinforced concrete have been limited, but experience, together with the results of tests thus far made, indicates that concrete, on account of its low rate of heat-conductivity and the fact that it is incombustible, may be used safely for fireproofing purposes. The dehydration of concrete probably begins at about 500° F. and is completed at about 900° F.; but experience indicates that the volatilization of the water absorbs heat from the surrounding mass, which, together with the resistance of the air-cells, tends to increase the heat-resistance of the concrete, so that the process of dehydration is very much re-

* See, also, Chapter XXIII, pages 817 and 818.

tarded. The concrete that is actually affected by fire remains in position and affords protection to the concrete beneath it. The thickness of the protective coating required depends on the probable duration of a fire which is likely to occur in the structure and should be based on the rate of heat-conductivity. The question of the conductivity of concrete is one which requires further study and investigation before a definite rate for different classes of concrete can be fully established. However, for ordinary conditions it is recommended that the metal in girders and columns be protected by a minimum of 2 in of concrete; that the metal in beams be protected by a minimum of 1½ in of concrete, and the metal in floor-slabs be protected by a minimum of 1 in of concrete. It is recommended that in monolithic concrete columns, the concrete to a depth of 1½ in be considered as protective covering and not included in the effective section. It is recommended that the corners of columns, girders and beams be beveled or rounded, as a sharp corner is more seriously affected by fire than a round one."

Waterproofing Concrete. "Many expedients have been used to render concrete impervious to water under normal conditions, and also under pressure-conditions that exist in reservoirs, dams and conduits of various kinds. Experience shows, however, that where mortar or concrete is proportioned to obtain the greatest practicable density and is mixed to a rather wet consistency, the resulting mortar or concrete is impervious under moderate pressure. A concrete of dry consistency is more or less pervious to water, and compounds of various kinds have been mixed with the concrete, or applied as a wash to the surface for the purpose of making it water-tight. Many of these compounds are of but temporary value, and in time lose their power of imparting impermeability to the concrete. In the case of subways, long retaining-walls and reservoirs, provided the concrete itself is impervious, cracks may be so reduced by horizontal and vertical reinforcement properly proportioned and located, that they are too minute to permit leakage or are soon closed by infiltration of silt. Coal-tar preparations applied either as a mastic or as a coating on felt or cloth-fabric are used for waterproofing, and should be proof against injury by liquids or gases. For retaining-walls and similar walls in direct contact with the earth, the application of one or two coatings of hot coal-tar pitch to the thoroughly dried surface of concrete is an efficient method of preventing the penetration of moisture from the earth." (See, also, Waterproofing for Foundations, Part III, pages 1629 to 1637.)

Surface-Finish of Concrete. "Concrete is a material of an individual type and should not be used in imitation of other structural materials. One of the important problems connected with its use is the character of the finish of exposed surfaces. The finish of the surface should be determined before the concrete is placed, and the work conducted so as to make possible the finish desired. For many forms of construction the natural surface of the concrete is unobjectionable; but frequently the marks of the boards and the flat, dead surface are displeasing, thus making some special treatment desirable. A treatment of the surface either by scrubbing it while green or by tooling it after it is hard, which removes the film of mortar and brings the aggregates of the concrete into relief, is frequently used to remove the form-markings, break the monotonous appearance of the surface, and make it more pleasing. The plastering of surfaces should be avoided, for even if carefully done, the plaster is likely to peel off under the action of frost or temperature-changes."

Design of Massive Concrete. "In the design of massive or plain concrete, no account should be taken of the tensile strength of the material, and sections should usually be proportioned, so as to avoid tensile stresses, except in slight

amounts, to resist indirect stresses. This will generally be accomplished, in the case of rectangular shapes, if the line of pressure is kept within the middle third of the section, but in very large structures, such as high masonry dams, a more exact analysis may be required. Structures of massive concrete are able to resist unbalanced lateral forces by reason of their weight; hence the element of weight rather than strength often determines the design. A relatively cheap and weak concrete, therefore, will often be suitable for massive concrete structures. It is desirable generally to provide joints at intervals to localize the effect of contraction. Massive concrete is suitable for dams, retaining-walls, and piers and short columns in which the ratio of length to least width is relatively small. Under ordinary conditions this ratio should not exceed six. It is also suitable for arches of moderate span, where the conditions as to foundations are favorable."

Quantities of Materials Required per Cubic Yard of Concrete.* The following tables give the quantities of Portland cement required to make 1 cu yd of mortar and the quantities of cement, sand and stone required to make 1 cu yd of concrete. They are based upon formulas deduced by Halbert P. Gillette.

Barrels of Portland Cement per Cubic Yard of Mortar

Voids in sand, 35%, 1 bbl of cement yielding 3.65 cu ft of cement paste

Proportion of cement to sand	1 to 1	1 to 1½	1 to 2	1 to 2½	1 to 3	1 to 4
	bbl	bbl	bbl	bbl	bbl	bbl
Barrel specified to be 3.5 cu ft	4.22	3.49	2.97	2.57	2.28	1.76
Barrel specified to be 3.8 cu ft	4.09	3.33	2.81	2.45	2.16	1.62
Barrel specified to be 4.0 cu ft	4.00	3.24	2.73	2.36	2.08	1.54
Barrel specified to be 4.4 cu ft	3.81	3.07	2.57	2.27	2.00	1.40
Cubic yard of sand per cu yd of mortar............	0.6	0.7	0.8	0.9	1.0	1.0

Barrels of Portland Cement per Cubic Yard of Mortar

Voids in sand, 45%, 1 bbl of cement yielding 3.4 cu ft of cement paste

Proportion of cement to sand	1 to 1	1 to 1½	1 to 2	1 to 2½	1 to 3	1 to 4
	bbl	bbl	bbl	bbl	bbl	bbl
Barrel specified to be 3.5 cu ft	4.62	3.80	3.25	2.84	2.35	1.76
Barrel specified to be 3.8 cu ft	4.32	3.61	3.10	2.72	2.16	1.62
Barrel specified to be 4.0 cu ft	4.19	3.46	3.00	2.64	2.05	1.54
Barrel specified to be 4.4 cu ft	3.94	3.34	2.90	2.57	1.86	1.40
Cubic yard of sand per cu yd of mortar..............	0.6	0.8	0.9	1.0	1.0	1.0

"In using these tables remember that the proportion of cement to sand is by volume and not by weight. If the specifications state that a barrel of cement shall be considered to hold 4 cu ft, for example, and that the mortar shall be

* Quoted, by permission, from the Handbook of Cost Data for Contractors and Engineers, by Halbert P. Gillette, published by The Myron C. Clark Publishing Company, Chicago, Ill. See 1914 revised edition, pages 538 to 540. This handbook contains complete and voluminous data on quantities, costs, etc., of building materials and operations.

1 part cement to 2 parts sand, then 1 bbl of cement is mixed with 8 cu ft of sand, regardless of what is the actual size of the barrel, and regardless of how much cement paste can be made with a barrel of cement. If the specifications fail to state what the size of a barrel will be, then the contractor is left to guess.

"If the specifications call for proportions by weight, assume a Portland cement barrel to contain 380 lb of cement, and test the actual weight of a cubic foot of the sand to be used. Sand varies extremely in weight, due both to the variation in the per cent of voids, and to the variation in the kind of minerals of which the sand is composed. A quartz sand having 35% voids weighs 107 lb per cu ft; but a quartz sand having 45% voids weighs only 91 lb per cu ft. If the weight of the sand must be guessed at, assume 100 lb per cu ft. If the specifications require a mixture of 1 part of cement to 2 parts of sand, by weight, we will have 380 lb (or 1 bbl) of cement mixed with 2 times 380, or 760 lb of sand; and if the sand weighs 90 lb per cu ft, we shall have 760 divided by 90, or 8.44 cu ft of sand to every barrel of cement. In order to use the tables above given, we may specify our own size of barrel; let us say 4 cu ft; then, 8.44 divided by 4 gives 2.11 parts of sand by volume to 1 part of cement. Without material error we may call this a 1 to 2 mortar, and use the tables, remembering that our barrel is now 'specified to be' 4 cu ft. If we have a brand of cement that yields 3.4 cu ft of paste per bbl and sand having 45% voids, we find that approximately 3 bbl of cement per cu yd of mortar will be required.

"It should be evident from the foregoing discussions that no table can be made, and no rule can be formulated that will yield accurate results unless the brand of cement is tested and the percentage of voids in the sand determined. This being so, the sensible plan is to use the tables merely as a rough guide, and, where the quantity of cement to be used is very large, to make a few batches of mortar, using the available brands of cement and sand in the proportions specified. Ten dollars spent in this way may save a thousand, even on a comparatively small job, by showing what cement and sand to select."

Ingredients in One Cubic Yard of Concrete *

Sand-voids, 40%; stone-voids, 45%; Portland-cement barrel yielding 3.65 cu ft paste. Barrel specified to be 3.8 cu ft

Proportions by volume	1 : 2 : 4	1 : 2 : 5	1 : 2 : 6	1 : 2½ : 5	1 : 2½ : 6	1 : 3 : 4
Barrels cement per cu yd concrete	1.46	1.30	1.18	1.13	1.00	1.25
Cubic yard sand per cu yd concrete	0.41	0.36	0.33	0.40	0.35	0.53
Cubic yard stone per cu yd concrete	0.82	0.90	1.00	0.80	0.84	0.71
Proportions by volume	**1 : 3 : 5**	**1 : 3 : 6**	**1 : 3 : 7**	**1 : 4 : 7**	**1 : 4 : 8**	**1 : 4 : 9**
Barrels cement per cu yd concrete	1.13	1.05	0.96	0.82	0.77	0.73
Cubic yard sand per cu yd concrete	0.48	0.44	0.40	0.46	0.43	0.41
Cubic yard stone per cu yd concrete	0.80	0.88	0.93	0.80	0.86	0.92

* This table is to be used where cement is measured packed in the barrel, for the ordinary barrel holds 3.8 cu ft.

"It will be seen that the above table can be condensed into the following:

"**Rule.** Add together the number of parts and divide this sum into ten, the quotient will be, approximately, the number of barrels of cement per cubic yard.

"Thus for a 1 : 2 : 5 concrete, the sum of the parts is 1 plus 2 plus 5, which is 8; then 10 divided by 8 is 1.25 bbl, which is approximately equal to the 1.30 bbl given in the table. Neither this rule nor this table is applicable if a different size of cement-barrel is specified, or if the voids in the sand or stone differ materially from 40% and 45% respectively. There are such innumerable combinations of varying voids, and varying sizes of barrels, that the author does not deem it worth while to give other tables."

Ingredients in One Cubic Yard of Concrete *

Sand-voids, 40%; stone-voids, 45%; Portland-cement barrel yielding 3.65 cu ft of paste. Barrel specified to be 4.4 cu ft

Proportions by volume	1 : 2 : 4	1 : 2 : 5	1 : 2 : 6	1 : 2½ : 5	1 : 2½ : 6	1 : 3 : 4
Barrels cement per cu yd concrete	1.30	1.16	1.00	1.07	0.96	1.08
Cubic yard sand per cu yd concrete	0.42	0.38	0.33	0.44	0.40	0.53
Cubic yard stone per cu yd concrete	0.84	0.95	1.00	0.88	0.95	0.71
Proportions by volume	**1 : 3 : 5**	**1 : 3 : 6**	**1 : 3 : 7**	**1 : 4 : 7**	**1 : 4 : 8**	**1 : 4 : 9**
Barrels cement per cu yd concrete	0.96	0.90	0.82	0.75	0.68	0.64
Cubic yard sand per cu yd concrete	0.47	0.44	0.40	0.49	0.44	0.42
Cubic yard stone per cu yd concrete	0.78	0.88	0.93	0.86	0.88	0.95

* This table is to be used when the cement is measured loose, after dumping it into a box, for under such conditions a barrel of cement yields 4.4 cu ft of loose cement.

Cost of Concrete. (For Cost of Cement, see page 238.) The average cost of sand may be taken at 30 cts per cu yd to cover digging and loading, but when washed or screened the cost averages between 40 and 55 cts per cu yd. Hauling and freight-charges generally raise the cost of sand, ready to unload at the site, to from 90 cts to $1.10 per cu yd, and about 15 cts per yd additional must be added, if unloaded from cars. Gravel costs from $1.20 to $1.40 per cu yd, unloaded at the job, and crushed stone from $1.45 to $1.60. These prices are, of course, average prices only, and include moderate-haul teaming and unloading. For hand-mixing and placing of soft concrete, and spreading without any ramming, the labor-cost varies from 90 cts to $1.30 per cu yd. This is for handling in barrows materials that are conveniently at hand. This cost will be much higher for dry concrete, and hand-mixing costs may reach $2 or $3 per cu yd. For machine-mixing alone and with machines taking four bags to the batch, the cost of mixing may be even as low as 50 or 60 cts per cu yd. For placing alone, the cost is about 75 cts per cu yd; this includes wheeling the concrete, dumping it in place and spreading and spading it into forms. This cost could be almost doubled where unusual care had to be exercised to obtain a good surface and where there was an extra amount of spading. The costs

are reduced for heavy mass-concrete, and have been as low as 50 or 60 cts per cu yd for machine-mixing and placing together, by mixer and derrick or by tracks and cars. The following approximate schedule * of labor-costs for mixing and placing concrete is given by L. H. Allen of the Aberthaw Construction Company, in Professor Hool's excellent treatise:

For footings	$1.50 per cu yd
For floor-slabs not exceeding 4½ in in thickness	$1.60 per cu yd
For floor-slabs exceeding 5 in in thickness	$1.00 per cu yd
For columns and thin walls	$1.50 per cu yd
For walls exceeding 18 in in thickness	$1.00 per cu yd
For dams and thick retaining-walls	$0.70 per cu yd

For the unit cost due to the cost of the tools, plant and supplies, $1 may be taken as an average for jobs requiring from 4 000 to 10 000 cu yd of concrete. It varies, of course, with the character and magnitude of the work. The cost for this item is reduced in larger jobs, falling to 80 or even 70 cts per cu yd; and it is increased in operations of less magnitude to from $1 to $1.50 per cu yd, for, say, 3 000 cu yd of concrete. When the amount of concrete required is as small as 600 or 700 cu yd, hand-mixing is generally more economical than machine-mixing. Mr. Allen summarizes * the cost of 1 cu yd of concrete for a building requiring 5 000 cu yd of reinforced-concrete work in floors and columns as follows, the cost of forms and steel and finishing of the surface not being included:

Cement, 1⅔ bbl, at $1.38 per bbl	$2.30
Sand, ½ cu yd, at $1 per cu yd	0.50
Stone, 1.35 tons, at $1.40 per ton	1.89
Labor, per cu yd	1.35
Plant, per cu yd	1.00
Total, per cu yd	$7.04

In this summary the exact theoretical proportions or quantities of cement, sand and stone required for 1 cu yd of concrete, and deduced from formulas, are not adhered to, the author stating that the exact theoretical proportions are the net quantities of the materials determined by careful experiment, that "conditions on actual construction work do not approach those of laboratory work and that there is always a considerable waste of cement, sand and stone." In view of these facts, he states that, "when estimating quantities, it is not safe to allow less than the following amounts of cement for different proportions of mix:

1 : 1½ : 3 mix	2.00 bbl per cu yd
1 : 2 : 4 mix	1.66 bbl per cu yd
1 : 2½ : 5 mix	1.40 bbl per cu yd
1 : 3 : 6 mix	1.20 bbl per cu yd"

It is customary to allow ½ cu yd of sand and 1 cu yd of crushed stone, to 1 cu yd of concrete, and to estimate the weight of crushed stone at 100 lb per cu ft.

The Weight of Concrete varies from 110 to 155 lb per cu ft, according to the material used. Concrete of the usual proportions weighs from 140 to 150 lb per cu ft. Trap-rock concrete weighs from 148 to 155; limestone or gravel concrete, from 142 to 148; and cinder concrete from 80 to 115 lb per cu ft.

* Reinforced Concrete Construction, by George A. Hool, McGraw-Hill Book Company, New York.

The Strength of Concrete. See Chapter V.

Earlier Examples of Portland-Cement Concrete. From the foregoing it is seen that for foundation-work to-day, mass-concrete varies in proportions from a 1 : 3 : 6 to a 1 : 4 : 8 mix. Some of the earlier examples are added for comparison.

Foundations of the United States Naval Observatory, Georgetown, D. C.: 1 part cement, 2½ sand, 3 gravel, 5 broken stone. (1 bbl of cement, 380 lb, made 1.18 yd of concrete.)

Foundations of the Cathedral of St. John the Divine, New York: 1 part Portland cement, 2 parts sand, 3 parts quartz gravel of pieces from 1½ to 2 in in diameter. (17 000 bbl of cement made 11 000 yd of concrete.)

Manhattan Life Insurance Building, New York, filling of caissons: 1 part Alsen Portland cement, 2 parts sand, 4 parts broken stone.

Johnston Building (15 stories), New York, filling of caissons: 1 part Portland cement, 3 parts sand, 7 parts stone, finished on top for brickwork with 1 part cement and 3 parts gravel.

Professor Baker states that the concrete foundations under the Washington Monument were made of 1 part Portland cement, 2 parts sand, 3 parts gravel and 4 parts broken stone, and that this mixture stood, when six months old, a load of 2 000 lb per sq in, or 144 tons per sq ft.

CHAPTER IV

RETAINING-WALLS, BREAST-WALLS AND VAULT-WALLS

By

GRENVILLE TEMPLE SNELLING

MEMBER OF AMERICAN INSTITUTE OF ARCHITECTS

1. Mechanical Principles Involved

General Principles. Before discussing more in detail the problems relating to masonry structures, in which, if improperly constructed, a tendency to slide or overturn on their bases may be developed, a familiarity with what are known as the THEOREM OF FRICTION and the THEOREM OF THE MIDDLE THIRD will be of assistance in comprehending the methods indicated for rendering such structures stable.

Theorem of Friction. If a body rests on an inclined plane it will remain stationary until the angle ϕ, that the plane makes with the horizontal,

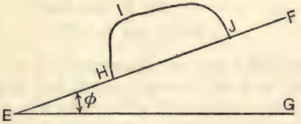

Fig. 1

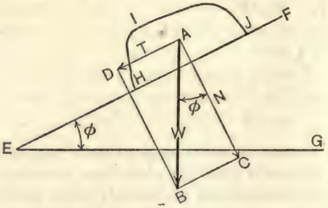

Fig. 2

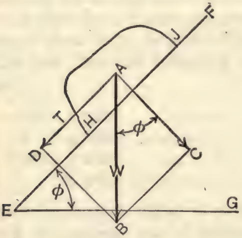

Fig.

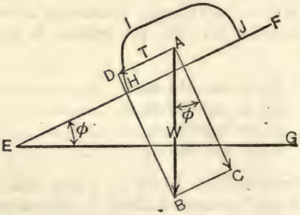

Fig. 4

Figs. 1, 2, 3 and 4. Body on Inclined Plane. Graphical Representation of Forces

becomes so great that the FRICTION developed between the surfaces of the body and the plane is no longer sufficient to prevent the body from sliding down the plane (Fig. 1).

Assume the body HIJ resting on the plane EF. The weight, W, of this body is shown graphically by the line AB, applied at its center of gravity A (Fig. 2).

This weight can be resolved into two component forces, one, AC, normal to the inclined plane and the other, AD, parallel to it. It is the parallel or tangential force which tends to pull the body down the plane and which is resisted by the friction developed between the two surfaces. The friction developed between any two surfaces in contact depends upon the nature of the materials of which they are composed and the intensity of the forces pressing them together; and it resists the tendency to slide only up to a certain point. As the angle ϕ, which the inclined plane makes with the horizontal, increases, the tangential component T, of the weight W, increases, until it becomes greater than the frictional resistance, and the body moves down the plane (Fig. 3). From trigonometry,

$$T = W \sin \phi$$

$$N = W \cos \phi, \quad \text{or,} \quad T = N \tan \phi$$

There is evidently a position of the plane, intermediate between the positions shown in Figs. 1 and 3, in which the component force T is just balanced by the friction and in which the body remains at rest although just on the point of sliding (Fig. 4). If the angle which the inclined plane makes with the horizontal, at the moment when the body is just about to slide, be designated by ϕ, the friction developed between the two surfaces will be equal to $N \tan \phi$, since, when the angle of inclination of the plane to the horizontal is ϕ, the tangential component of the weight just balances the friction. From the equation $T = N \tan \phi$ it is evident that the friction is directly proportional to N and to $\tan \phi$. Tan ϕ is then known as the COEFFICIENT OF FRICTION and ϕ as the ANGLE OF REPOSE, or, in the case of stone surfaces, it is often known as the ANGLE OF FRICTION.

The following Table I gives the average values of these constants as determined by experiment.

Table I. Coefficients and Angles of Friction

Kind of surface	Coefficient of friction, tan ϕ	Angle of friction, ϕ
Granite, limestone and marble:		
Soft dressed upon soft dressed	0.70	35° 00′
Hard dressed upon hard dressed	0.55	28 50
Hard dressed upon soft dressed	0.65	33 00
Stone, brick or concrete:		
Masonry upon masonry	0.65	33 00
Masonry upon wood (with the grain)	0.60	31 00
Masonry upon wood (across the grain)	0.50	26 40
Masonry upon dry clay	0.50	26 40
Masonry upon wet or moist clay	0.33	18 20
Masonry upon sand	0.40	21 50
Masonry upon gravel	0.60	31 00
Soft stone upon steel or iron	0.40	21 50
Hard stone upon steel or iron	0.30	16 40

In this discussion only the weight AB (Figs. 2, 3 and 4), of the body has been considered; but the body might be subjected to the action of other forces besides the force of gravity, in which case these other forces would be combined with the weight in order to find the resultant, this resultant being again resolved into a tangential and a normal component. Since the angle BAC is equal to the

angle *FEG* (Figs. 2, 3 and 4), given a certain normal pressure exerted by the body on the plane, the amount of the tangential pressure T depends upon the angle *FEG*. The problem in actual practice reduces itself to so arranging the conditions that no matter what the position of the plane may be, the angle ϕ, which the resultant W, makes with the normal N, to the plane, will not be greater than the ANGLE OF FRICTION OR REPOSE.

Theorem of the Middle Third. When any surface is subjected to pressure from the action of any force or forces, this TOTAL PRESSURE may be considered as a SYSTEM OF AN INFINITE NUMBER OF PARALLEL FORCES, equal or unequal in intensity. These forces will have a RESULTANT, whose MAGNITUDE, DIRECTION and POINT OF APPLICATION can be determined, either graphically, or by moments, as explained in Chapter VI. The determination of these three elements of this resultant force may at times become of the utmost importance to the engineer.

Pressure of this nature is technically known as the STRESS to which the surface in question is subjected. (See Chapter I.) When the INTENSITY OF A STRESS is not the same at different points of a surface, it is called a VARYING STRESS, while if, on the contrary, its intensity remains the same at every point of the surface, it is called a UNIFORM STRESS.

When a stress varies it may do so in one or two ways. It may vary UNIFORMLY, that is to say, in a uniform manner, following some definite law of variation, so that, knowing this law, its intensity may be determined for any given point of the surface; or NON-UNIFORMLY, following no law. When a stress varies in the former manner it is called a UNIFORMLY VARYING STRESS This is the case most frequently met with in engineering problems.

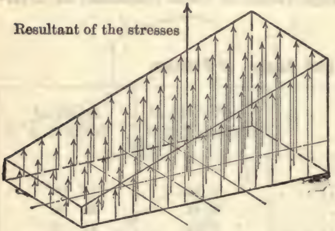

Fig. 5. Resultant within Middle Third

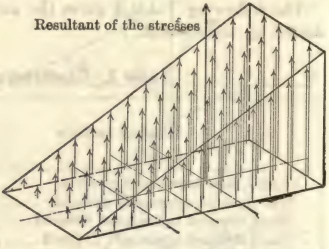

Fig. 6. Resultant at Middle Third

In dealing with ISOLATED FORCES, such as concentrated loads on a beam, we are usually interested in determining the MAGNITUDE and POINT OF APPLICATION of the RESULTANT of these forces. When, however, the question is one of STRESS, or of an unlimited number of forces, the problem that usually presents istelf is one in which the resultant is known, in magnitude, direction and point of application, and in which it is required to determine the DISTRIBUTION OF THE STRESS to which the surface is subjected. Or, in actual practice, it is required to so arrange the parts of the structure that this resultant shall have such a magnitude, direction and point of application that the stress to which the surface under consideration is subjected shall not exceed certain LIMITS OF SAFETY, determined beforehand by experience. For example, when the resultant of a known amount of pressure or stress acts at the CENTER OF GRAVITY of the surface subjected to the stress, this stress is UNIFORMLY DISTRIBUTED over the surface.

When the resultant acts at a distance of two-thirds the total width of the surface from one edge or boundary line of the surface, and at one-third the width from the other edge, the stress is UNIFORMLY VARYING; and its INTENSITY at the edge farthest from the point of application of the resultant is ZERO and at the other edge a MAXIMUM or twice the average stress. When, however, the total amount of the stress remaining the same, the point of application of the resultant is at a greater distance from one edge than two-thirds the total width of the surface, a certain part of the surface adjacent to the edge furthest from the resultant is subjected to a STRESS OF A CONTRARY NATURE to that distributed over the rest of the area; that is to say, if the stress to which the major part of the surface is subject is a COMPRESSIVE stress, the stress acting on the remainder of the surface is a TENSILE stress. The stresses in a surface resulting from three different positions of the resultant force may be illustrated graphically, as shown in Figs. 5, 6 and 7.

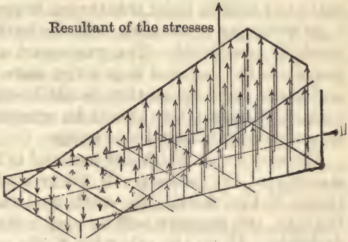

Fig. 7. Resultant beyond Middle Third

2. Retaining-Walls

Definitions. A RETAINING-WALL is a wall built to resist the pressure of earth, sand, or other filling or backing deposited behind it after it is built, as distinguished from a BREAST-WALL or FACE-WALL, which is a similar structure built to prevent the fall of earth which is in its undisturbed, natural position, but from which part has been excavated, leaving a vertical or inclined face. Fig. 8 is an illustration of the two kinds of wall.

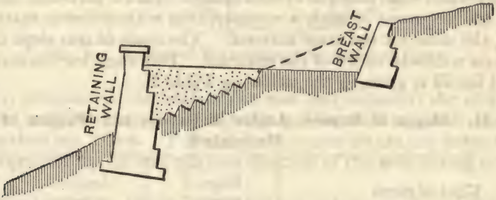

Fig. 8. Retaining-wall and Breast-wall

Theories of Retaining-Walls. A great deal has been written on the THEORY OF RETAINING-WALLS, and many theories, involving elaborate calculations for determining the CONJUGATE PRESSURES in the earth-backing behind the wall, have been developed for computing the THRUST which a bank of earth exerts against such a wall, and for determining the FORM of wall which offers the greatest resistance with the least amount of material. There are so many conditions, however, upon which the thrust exerted by the backing depends, such as the cohesion of the earth, the dryness of the material, the mode of backing up the wall, etc., that in practice it is impossible to determine the exact thrust which will be exerted against a wall of a given height. It is necessary, therefore, in designing retaining-walls, to be guided by experience rather than by theory. As the theories of retaining-walls are so vague and unsatisfactory, we shall not

include any in this work, but offer, rather, such suggestions, rules and cautions as have been established by practice and experience. A construction suggested from empirical data, which has been found to work well in practice, for determining the THRUST OF THE EARTH-BACKING and the DIMENSIONS OF THE WALL to properly resist this thrust, is given on page 257.

In designing a retaining-wall the backing as well as the wall itself must be carefully considered. THE TENDENCY OF THE BACKING TO SLIP is very much less when the material is in a dry state than when it is saturated with water, and hence every precaution should be taken to secure good drainage. Besides surface-drainage, there should be openings left in the wall for the water which may accumulate behind it to escape.

The manner in which the material is filled against the wall, also, affects the stability of the backing. If the ground is made irregular, with steppings, as shown in Fig. 8, and the earth well rammed in layers inclined DOWN FROM the wall, the pressure will be very trifling, provided that attention is paid to drainage. If, on the other hand, the earth is tipped in the usual manner, in layers sloping DOWN TOWARDS the wall, almost the full pressure of the earth will be exerted against it, and it must be made strong enough to withstand such pressure.

Slopes of Repose and Angles of Repose. Cases may occur in practice in which the conditions are not such as are shown in Fig. 8, which shows only a limited amount of fill or new material put in behind the wall on top of the original slope of the grade; cases in which, on the contrary, the wall has been built on the natural surface of the ground with a view to creating an entirely new terrace or embankment and where all the material back of the wall is new.

All of this material does not beat upon the wall and tend to overturn it, for sand or loose earth taken from an excavation and deposited on the surface of the ground does not spread itself out like a liquid but piles up in a mound. This PILING UP is due to the FRICTION developed between the separate particles as they slide one over the other while being dumped. This phenomenon is observed in the action of any solid material broken up into separate particles; and although the SLOPE OF THE SIDES of such a mound varies with different materials, it is, in general, the same for the same material. The angle of this slope is known as the ANGLE OF NATURAL SLOPE of the material. This angle for the materials generally used for fill is given in the following Table II.

Table II. Slopes of Repose, Angles of Repose and Weights of Loose Materials

Kind of earth	Slope of repose*	Angle of repose	Weight in lb per cu ft
Sand, clean	1.5 to 1	33° 41′	90
Sand and clay	1.33 to 1	36 53	100
Clay, dry	1.33 to 1	36 53	100
Clay, damp, plastic	2 to 1	26 34	100
Gravel, clean	1.33 to 1	36 53	100
Gravel and clay	1.33 to 1	36 53	100
Gravel, sand and clay	1.33 to 1	36 53	100
Soil	1.33 to 1	36 53	100
Soft rotten rock	1.33 to 1	36 53	110
Hard rotten rock	1 to 1	45 00	100
Bituminous cinders	1 to 1	45 00	65
Anthracite ashes	1 to 1	45 00	30

* The slope is that of horizontal to vertical projection.

Pressures on Retaining-Walls. Even under the conditions shown in Fig. 8, only a part of the filled-in material will exert a pressure on the wall. It would be natural to suppose that the part of the fill exerting pressure on the wall would be determined by the ANGLE OF NATURAL SLOPE, all material from a natural horizontal grade up to this angle being able to take care of itself, and all the material above the angle needing the wall to hold it in place. Experiment shows that this is not strictly true, for as the earth settles into place certain forces of INTERNAL ELASTICITY and tendencies toward a state of EQUILIBRIUM come into play creating INTERNAL STRESSES which produce the CONJUGATE PRESSURES already referred to. The exact determination of these INTERNAL STRESSES demands relatively complicated calculations which would be out of place in a book of this character. The construction given in the following paragraphs for determining the SLOPE OF THE CLEAVAGE-PLANE, between that part of the backing which sustains itself and the triangular fill which actually bears on the wall, is sufficiently accurate, however, for all practical purposes.

The Slope of the Cleavage-Plane. The following construction (Figs. 9 and 10), based upon empirical data, for determining first, the PRISM OF EARTH

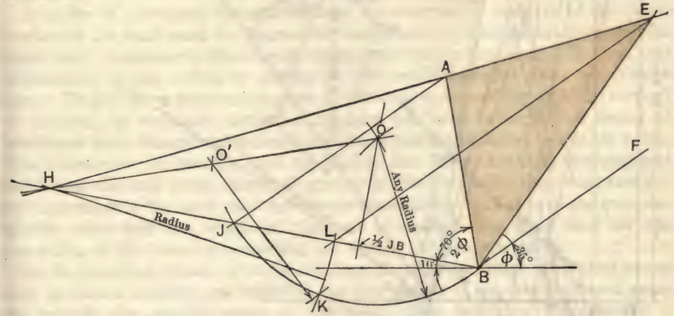

Fig. 9. Method of Determining the Prism of Earth

which exerts pressure on the back of the wall and secondly, the proper DIMENSIONS for the wall, has been found to work well in practice, when certain necessary precautions are taken. These include proper DRAINAGE behind the wall, proper RAMMING of the fill and efficient BRACING of the wall during its construction.

In the calculations to determine the pressure of the earth and the weight of the wall, a slice 1 ft thick is first considered. Then the area of the triangle ABE is proportional to the volume and weight of the slice of earth causing pressure on the wall, and as the area of the cross-section of the wall is proportional to the volume and weight of the slice of the wall itself.

To determine the PRISM OF EARTH which exerts pressure against the back of the wall, decide first upon the BATTER to be given to the back of the wall. In this case it made 80° with the horizontal, an angle slightly greater than that advised by Trautwine. Draw BH (Fig. 9), making an angle ABH, equal to 2ϕ, with the back of the wall; continue this line until it meets at H the slope of the surface of the earth back of the wall, prolonged. From A, the top of the wall, draw AJ parallel to BF the natural slope of the fill. This has been taken at 35°, as a fair average value. Erect a perpendicular from the middle of JB, and with any point, O, as a center, on this perpendicular, describe an arc passing

through J and B. Draw HO and bisect it, and with O' as a center and OO' as a radius, describe the arc cutting the arc JKB at K. Again, with a radius HK and with H as center, describe the arc KL, and finally, from L, draw LE parallel to JA. The intersection of this line with the surface of the ground locates the

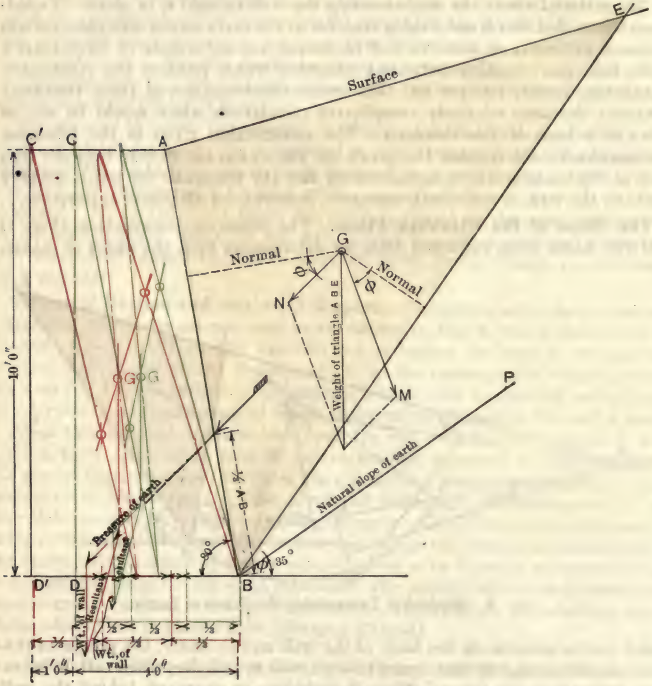

Fig. 10. Method of Determining Dimensions of Retaining-wall

point E. The line EB is the line of the CLEAVAGE-PLANE which separates the part of the backing which bears against the wall from the part which exerts no lateral pressure.

Having found the DIMENSIONS OF THE VOLUME OF EARTH, the thrust of which must be resisted by the wall, the next step is to determine what the DIMENSIONS OF THE WALL should be to properly resist this thrust. Usually one or two trials are necessary before the proper solution of the problem is found. In the example given, a preliminary trial was made with a thickness at the base of 4 ft. This construction is shown with the green lines (Fig. 10).

After drawing the triangle representing the base of the PRISM OF EARTH, find its center of gravity, G (Chap. VI). From this point draw two normals, one to the back of the wall and the other to the line of the CLEAVAGE-PLANE. Draw the two lines, GM and GN, making angles ϕ with these normals. Lay off vertically from the center of gravity, at any convenient scale of so many square

inches to the linear inch, the area of the triangle of the base of the prism, the area, as already explained, being proportional to the volume of the prism and its weight. Resolve this weight-line along the two lines *GM* and *GN* (Chap. VI). This will give the MAGNITUDE and DIRECTION of the THRUST or pressure of the earth against the wall. Apply this pressure at a point on the back of the wall one-third of the distance from the bottom, as shown by the arrow. This is the force which may tend to OVERTURN the wall and which tends to make it SLIDE along the base.

To resist these OVERTURNING and SLIDING-TENDENCIES, the weight of the wall combined with the pressure of the earth behind it should produce a resultant which satisfies the following conditions. First, its MAGNITUDE should not be great enough to cause a unit pressure on the foundation-bed greater than it can safely bear; secondly, it should pass within the MIDDLE THIRD of the base so that the stress over the entire area of the base will be a COMPRESSIVE stress; and thirdly, it should make an angle with a normal to the plane of the foundation-bed not greater than the ANGLE OF FRICTION between the stone, brickwork, concrete, or other masonry of the footings and the sand, clay, or rock of the foundation-bed.

In order to determine these conditions, the CENTER OF GRAVITY of the cross-section of the wall must be determined and a vertical line drawn through this point until it intersects the line of the EARTH-THRUST produced. It is at this intersection of the LINES OF ACTION of the two forces that their RESULTANT acts. To find the CENTER OF GRAVITY of the cross-section of the wall, the method of dividing the trapezoid into two triangles has been followed, the center of gravity of each triangle being found and these two points being joined by a line. The intersection of this line with the median line drawn between the base and the top of the wall is the center of gravity of the trapezoid. In this example, for convenience, the scale used for the composition of the forces of the pressure of the earth and the weight of the wall is one-half the scale used for the resolution of the forces representing the weight of the earth-prism.

In the first trial, shown by the green lines, the first and third conditions necessary to insure stability are fulfilled; but the second is not, the resultant passing outside the MIDDLE THIRD of the base. This indicates, theoretically, a slight TENSILE stress or a tendency for the joints at the back of the wall to open. Another trial, therefore, is shown with the red lines, the thickness of the wall being increased as shown by the rectangle *CC'D'D*. In this second trial the WEIGHT OF THE WALL is necessarily increased while the EARTH-THRUST remains the same. As in this case the resultant passes within the middle third, it is concluded that a wall of these dimensions, 5 ft base by 10 ft height and with an 80° batter, will be safe and will properly resist the thrust of the earth-backing.

Details of Construction. Retaining-walls are generally built with a BATTERING, that is, a SLOPING face, as walls of this form are the strongest for a given amount of material; and if the courses are INCLINED DOWN TOWARDS THE BACK, the tendency to slide on each other will be resisted, and it will not be necessary to depend upon the adhesion of the mortar. The importance of making the resistance independent of the adhesion of the mortar is obviously very great, as it would otherwise be necessary to delay the backing up of the wall until the mortar had thoroughly set, which might require several months.

In brickwork it is advisable to let every third or fourth course below the frost-line project an inch or two. This increases the friction of the earth against the back and causes the resultant of the forces acting behind the wall to become more nearly vertical, and to fall farther within the base, increasing the stability.

It also conduces to strength to make the courses of varying heights throughout the thickness of the wall, and to have some of the stones, especially those near the back, sufficiently high to extend through two or three courses. By this means the whole masonry becomes more effectually interlocked or bonded together as one mass and is less liable to bulge. The courses of masonry are often laid with their beds SLOPING IN, as in Fig. 15, to overcome the tendency of the courses to slide on each other.

Where the ground freezes to a great depth, the back of the wall should be SLOPED FORWARD for three or four feet below its top surface, as at *OC* (Fig. 11),

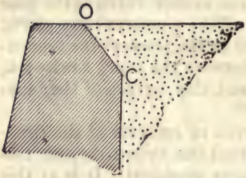

Fig. 11. Retaining-wall for Deep-freezing Earth

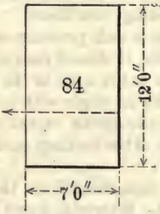

Fig. 12. Retaining-wall with Rectangular Cross-section

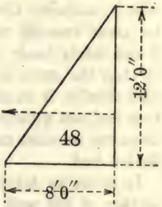

Fig. 13. Retaining-wall with Triangular Cross-section

and this slope should be quite smooth, so as to lessen the hold of the frost and prevent displacement.

Figs. 12, 13, 14 and 15 show the approximate RELATIVE VERTICAL SECTIONAL AREAS of walls of different shapes that would be required to resist the pressure of a bank of earth 12 ft high. The first three examples are calculated to resist the maximum thrust of wet earth, while the last shows the modified form usually adopted in practice.

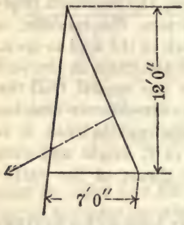

Fig. 14. Retaining-wall with Triangular Cross-section

Notes on the Thickness of Retaining-Walls. As has been stated, about the only practical rules for retaining-walls are the empirical rules based upon experience and tests. Trautwine* gives the following Table III for the thickness at the base of vertical retaining-walls with a sand backing deposited in the usual manner. The first column contains the vertical height *CD* (Fig. 16) of the earth as compared with the vertical height of the wall, *AB*. The latter is assumed to be 1, so that the table begins with a backing of the same height as the wall. These vertical walls may be battered to any extent not exceeding 1½ in to 1 ft, or 1 in 8, without affecting their stability and without increasing the base.

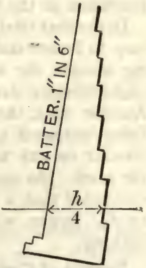

Fig. 15. Retaining-wall with Stepped Back

If the wall is built as in Fig. 17, with the ground practically level with the top, the top of the wall should be not less than 18 in thick, and the thicknesses at *a*, *a*, etc., just above each step, should be from one-third to two-fifths of the

* The Civil Engineer's Pocket-Book, John C. Trautwine.

Table III. Proportions of Retaining-Walls
(Thickness of wall at the base in parts of the height, AB, Fig. 16)

Total height of the earth compared with the height of the wall above ground	Wall of cut stone in mortar	Wall of rubble or brick, good mortar	Wall of good, dry rubble
1	0.35	0.40	0.50
1.1	0.42	0.47	0.57
1.2	0.46	0.51	0.61
1.3	0.49	0.54	0.64
1.4	0.51	0.56	0.66
1.5	0.52	0.57	0.67
1.6	0.54	0.59	0.69
1.7	0.55	0.60	0.70
1.8	0.56	0.61	0.71
2	0.58	0.63	0.73
2.5	0.60	0.65	0.75
3	0.62	0.67	0.77
4	0.63	0.68	0.78
6	0.64	0.69	0.79
14	0.65	0.70	0.80
25	0.66	0.71	0.81
or more	0.68	0.73	0.83

height from the top of the wall to each of these levels. If the earth is banked above the top of the wall, the thicknesses should be increased as indicated by the table given above. If built upon ground that is affected by frost or surface-water, the footings should be carried sufficiently below the surface of the ground at the base to insure against heaving or settling.

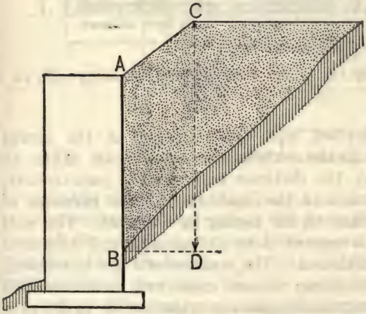

Fig. 16. Retaining-wall with Raised Sand Backing

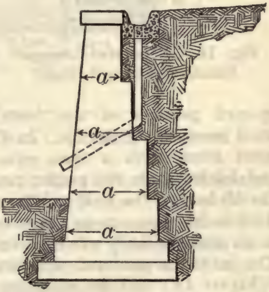

Fig. 17. Retaining-wall with Stepped Back

Reinforced-Concrete Retaining-Walls. With the constantly increasing use of REINFORCED CONCRETE for various purposes, there has come, also, the construction of retaining-walls in this material. Figs. 18,* 19* and 20* show three designs by A. L. Johnson for retaining-walls to satisfy the

* Plain and Reinforced Concrete, Taylor and Thompson.

requirements of banks 5, 10 and 20 ft high. The wall shown in Fig. 20 is reinforced at intervals with COUNTERFORTS. The walls themselves in Figs. 18 and 19 act as CANTILEVER BEAMS. The FOOTINGS, in all three cases, are subjected to two principal external forces, the resultant of the resisting

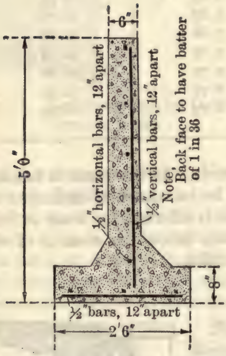

Fig. 18. Reinforced-concrete Retaining-wall, 5 ft High

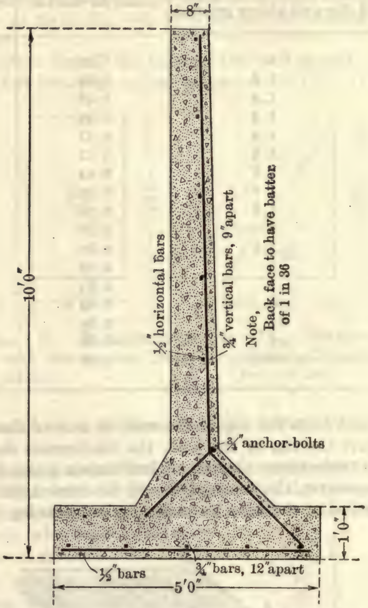

Fig. 19. Reinforced-concrete Retaining-wall, 10 ft High

upward pressure of the foundation-bed and the resultant of the downward pressures of the fill. In Fig. 20 the COPING acts as a BEAM FIXED AT BOTH ENDS, with a span equal to the distance between the counterforts, and loaded with the proper proportion of the load due to the pressure of the fill behind the wall and transmitted to the coping by the wall. The wall itself in this case acts as a FLOOR-SLAB supported on all four sides and subjected to an approximately evenly distributed load. The counterforts are in tension. The MAXIMUM BENDING MOMENTS for these various cases can be determined (Chapter IX) and the necessary DIMENSIONS and REINFORCEMENT to be provided decided by the rules given in Chapter XXIV.

3. Breast-Walls

Breast-Walls. Where the ground to be supported is firm, and the strata are horizontal, the office of a BREAST-WALL (Fig. 8) is more to protect than to sustain the earth. It should be borne in mind that a trifling force skilfully applied to unbroken ground will keep in its place a mass of material, which, if once allowed to move, would crush a heavy wall. Great care, therefore, should be taken not to

expose the newly opened ground to the influence of air and water longer than is requisite for sound work, and to avoid leaving the smallest space for motion between the back of the wall and the ground. The strength of a breast-wall must be proportionately increased when the strata to be supported incline down

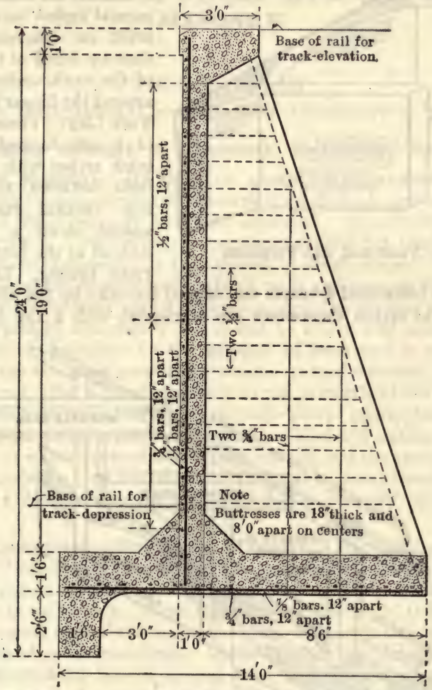

Fig. 20. Reinforced-concrete Retaining-wall with Counterforts and Apron

towards the wall; where they incline down from it, the wall need be little more than a THIN FACING to protect the ground from disintegration. The preservation of the NATURAL DRAINAGE is one of the most important points to be attended to in the erection of breast-walls, as upon this their stability in a great measure depends. No rule can be given for the best way to do this; it is a matter for attentive consideration in each particular case.

4. Vault-Walls

Vault-Walls. In large cities it is customary to utilize the space under the sidewalk for storage or other purposes. This necessitates a wall at the curb-line to hold back the earth and the street-pressures and also the weight of the sidewalk. Where practicable the space should be divided by partition-walls about every 10 ft, and when this is done the outer wall may be advantageously built of hard bricks in the form of arches, as shown in Fig. 21. The THICKNESS

of the arch should be at least 16 in for a depth of 9 ft and the RISE of the arch from one-eighth to one-sixth of the span. If partitions are not practicable, each sidewalk-beam may be supported by a heavy **I**-beam column, with either flat or segmental arches between, of either brick or concrete. Fig. 22 * shows a detail of the outer walls of the vault under the sidewalk around the Singer building, New York City. These walls consist of a core formed by two-ring brick arches with vertical axes, built between the flanges of 8-in vertical steel **I** beams spaced about 5 ft apart and bedded at the bottom in a concrete footing. Their tops are joined by 6-in horizontal **I** beams and braced laterally by the sidewalk-beams, 5 ft apart. The arches themselves are segmental, with a rise of about 6 in,

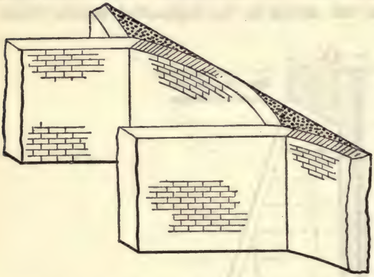

Fig. 21. Vault-wall with Partitions

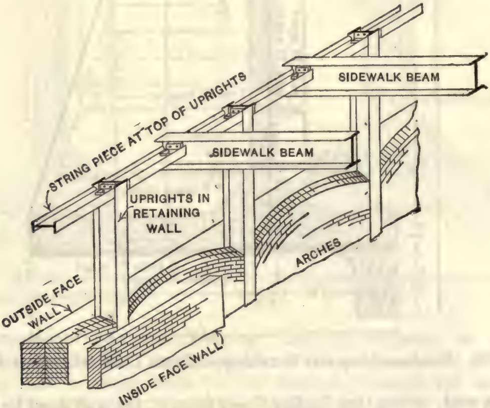

Fig. 22. Vault-walls of Singer Building, New York City

and are built up solid against an 8-in outside face-wall. A 4-in plain curtain wall is built inside against the flanges of the vertical beams, inclosing segmental air-chambers in front of each arch.

* From The Engineering Record, Feb. 26, 1898.

CHAPTER V

STRENGTH OF BRICK, STONE, MASS-CONCRETE AND MASONRY

By

THOMAS NOLAN

PROFESSOR OF ARCHITECTURAL CONSTRUCTION, UNIVERSITY OF PENNSYLVANIA

1. Crushing Strength of Stonework, Brickwork, Bricks, etc.

Stresses in Masonry. By the term STRENGTH OF MASONRY is generally meant its resistance to a direct COMPRESSIVE force or load, and this is the only direct stress to which masonry should be subjected. Stone lintels and footings may be subjected to a TRANSVERSE OF BENDING STRESS, but they can hardly be included in the term masonry, as they consist of single pieces. There are also tendencies to bend and to split apart in brick walls and piers, as they are usually high in proportion to their lateral dimensions, but the stresses thus developed cannot be accurately determined and should be avoided as much as possible. It is impossible to fix values for the strength of brickwork or stonework with anything like the exactness possible for wooden or steel members, for the reason that there is not only a great variation in the strength of different kinds of brick and stone, even when taken from the same kiln or quarry, but the strength of walls and piers is also greatly affected by the kind and quality of the mortar used, the way in which the work is built and bonded, and the amount of moisture in the materials when they are laid. All that can be done, therefore, is to give values which will be safe for the different kinds of masonry built in the usual manner.

Working Compressive Strength of Masonry. The building laws of most of the larger cities of this country specify the maximum loads per square foot allowed to be placed upon different kinds of masonry, and these laws must govern the architects in such cities. When there is no restriction of this kind, Table I gives a pretty good idea of the maximum loads which it is safe to put upon the different kinds of work mentioned. Table II gives the maximum safe loads specified in the building laws of several cities, and the remaining tables of the chapter give records of numerous tests made to determine the ultimate compressive strengths of various kinds of bricks, building stones, mortars and concretes, and are of value in determining the safe loads for special cases. In determining the safe compressive resistance of masonry from tests on the ultimate compressive strength of work of the same kind, a factor of safety of at least 10 should be allowed for piers and 20 for arches.

Table I. Safe Working Loads for Masonry

BRICKWORK IN WALLS OR PIERS

	Tons per square foot Eastern	Tons per square foot Western
Red brick in lime mortar	7	5
Red brick in hydraulic-lime mortar	...	6
Red brick in natural-cement mortar, 1 : 3	10	8
Arch or pressed bricks in lime mortar	8	6
Arch or pressed bricks in natural-cement mortar	12	9
Arch or pressed bricks in Portland-cement mortar	15	12½

Piers exceeding in height six times their least lateral dimensions should be increased 4 in in lateral dimensions for each additional 6 ft.

STONEWORK

	Tons per square foot
Rubble walls, irregular stones	3
Rubble walls, coursed, soft stone	2½
Rubble walls, coursed, hard stone	5 to 16
Dimension-stone, squared, in cement mortar:	
Sandstone and limestone	10 to 20
Granite	20 to 40
Dressed stone, with ⅜-in dressed joints, in Portland-cement mortar:	
Granite	60
Marble or limestone, best	40
Sandstone	30

The height of columns should not exceed eight times the least diameter, unless the least diameter is sufficiently greater than necessary for the strength of the material used.

CONCRETE *

Portland-cement mortar, 1 : 8, 6 months, 10 tons; 1 year, 15 to 20 tons
Natural-cement mortar, 1 : 6, 6 months, 3 tons; 1 year, 5 to 8 tons

HOLLOW TILE

Safe loads per square inch of effective bearing parts

Hard fire-clay tiles	80 lb †
Hard ordinary clay tiles	60 lb
Porous terra-cotta tiles	40 lb

MORTAR

In ½-in joints, 3 months old

	Tons per square foot
Portland-cement mortar, 1 : 4	40
Natural-cement mortar, 1 : 3	13
Lime mortar, best	8 to 10
Best Portland-cement mortar, 1 : 2, in ¼-in joints for bedding iron plates	70

The values given above are generally very conservative. The leading architects and engineers of Chicago recommended for that city in 1908 the following SAFE WORKING PRESSURES for brick and stone masonry and concrete:

Common brick of crushing strength equal to 1 800 lb per sq in:	Lb per sq in	Tons per sq ft
In lime mortar	100	7⅕
In lime-and-cement mortar	125	9
In natural-cement mortar	150	10⅘
In Portland-cement mortar	175	12⅗

* See pages 283 to 287.
† These loads are allowed by the Chicago Building Ordinance.

	Lb per sq in	Tons per sq ft
Select, hard, common brick, of crushing strength equal to 2 500 lb per sq in:		
In 1 part Portland cement, 1 lime-paste and 3 sand.	175	12⅗
In 1 : 3 Portland-cement mortar..................	200	14⅖
Pressed and sewer-brick, of crushing strength equal to 5 000 lb per sq in:		
In 1 : 3 Portland-cement mortar..................	250	18
Paving brick, in 1 : 3 Portland-cement mortar.......	350	25⅕
Concrete, natural cement, 1 : 2 : 5..................	150	10⅘
Concrete, Portland cement, 1 : 3 : 6, machine-mixed..	300	21⅗
Concrete, Portland cement, 1 : 3 : 6, hand-mixed.....	250	18
Concrete, Portland cement, 1 : 2 : 4, machine-mixed..	400	28⅘
Concrete, Portland cement, 1 : 2 : 4, hand-mixed.....	350	25⅕
Rubble, uncoursed, in lime mortar..................	60	4⅓
Rubble, uncoursed, in Portland-cement mortar.......	100	7⅕
Rubble, coursed, in lime mortar....................	120	8½
Rubble, coursed, in Portland-cement mortar.........	200	14⅖
Ashlar, limestone, in Portland-cement mortar........	400	28⅘
Ashlar, granite, in Portland-cement mortar..........	600	43⅕

‡ According to mixture.
§ 1 : 2 : 5 mixture.

Brick Piers. As a rule brickwork is subject to its full safe resistance only when used in piers, and in small sections of walls, under bearing-plates. In the

latter case but a few courses receive the full load, and hence a greater unit stress may be allowed than for piers. Values for computing the area of bearing-plates are given in Chapter XIII. Aside from the quality of the work and materials the two elements which most influence the strength of brick piers are the ratio of height to least lateral dimension and the method of bonding. When the height of a brick pier exceeds six times its least lateral dimension the load per square foot should be reduced from the values given in Table I.

Formulas for the Safe Strength of Brick Piers exceeding six diameters in height. From the records of numerous tests on the strength of brick piers, from some formulas published* by Ira O. Baker, and also from personal observation, Mr. Kidder deduced the following formulas for the maximum working loads for first-class brickwork in piers whose height exceeds six times the least lateral dimension.

For piers laid with rich lime mortar:

$$\text{Safe load per square inch} = 110 - 5\,H/D \tag{1}$$

For piers laid with 1 : 2 natural-cement mortar:

$$\text{Safe load per square inch} = 140 - 5\tfrac{1}{2}\,H/D \tag{2}$$

For piers laid with 1 : 3 Portland-cement mortar:

$$\text{Safe load per square inch} = 200 - 6\,H/D \tag{3}$$

H representing the height in feet, and D the least lateral dimension in feet.†

For a pier 20 ft high and 2 ft square these formulas will reduce the safe load to 4.3 tons per sq ft for lime mortar, 6.1 tons for natural-cement mortar and 10 tons for Portland-cement mortar. No pier over 8 ft high should be less than 12 by 12 in in cross-section and when from 6 to 8 ft high piers should be at least 8 by 12 in in cross-section.

The following is the Chicago law (1914): "Isolated piers of concrete, brick or masonry shall not be higher than six times their smallest dimensions unless the above unit stresses ‡ are reduced according to the following formula:

$$P = C\,(1.25 - H/20\,D) \tag{4}$$

in which P is the reduced allowed unit load, C the unit stress above referred to, H the height of the pier in feet and D the least dimension of the pier in feet. No pier shall exceed in height twelve times the least dimension. The weight of the pier shall be added to other loads in computing the load on the pier."

Brick piers intended to carry more than 50% of the safe loads given above should not be built in freezing weather nor with dry bricks. Lime mortar should not be used for building piers that are to receive their full load within three months.

Effect of Bond on the Strength of Brickwork. Brick piers, loaded to the point of destruction, always fail by the splitting and bulging out of the

* In the Brickbuilder, April, 1898.

† For piers faced with pressed bricks, laid with joints ¼ in or less in thickness, and backed with common bricks in lime mortar, only the dimensions of the backing should be considered in figuring their strength. If the backing is laid in cement mortar and the face-bricks are well tied to the backing, the full section of the pier may be considered. For piers veneered with stone or terra-cotta, 4 in thick, only the strength of the backing should be considered.

‡ These are in general the "safe working pressures" for brickwork previously mentioned as recommended by the Chicago architects and engineers in 1908.

piers themselves, and not by direct crushing of the bricks or mortar, showing that piers are weakest in their bond and in the tensile or transverse strengths of the bricks. It is very important, therefore, to have the brickwork well bonded, and all joints filled with mortar or grouted. The strength of a brick pier intended to carry an extreme load would probably be increased by bonding frequently with hoop-iron in addition to the regular brick-bond.*

Bond-Stones in Brick Piers. Many competent architects and builders consider that the strength of a brick pier is increased by inserting bond-stones, from 5 to 8 in in thickness and the full size of the pier in cross-section, every 3 or 4 ft in height.

For example, the Building Laws for the City of New York (1906) require bond-stones every 30 in in height, and at least 4 in in thickness, to be built into brick piers which contain "less than 9 superficial feet at the base, and which support any beam, girder, arch, or column on which a wall rests, or lintel spanning an opening over 10 ft and supporting a wall." The New York laws allow cast-iron plates of sufficient strength and of the full cross-section of the pier to be used instead of the bond-stones. On the other hand, there are many first-class builders who consider that bond-stones in a brick pier do more harm than good, and the author is of the opinion that this is generally the case. The Boston Building Laws do not require intermediate bond-stones. If bond-stones are used, they should be bedded so as to bear rather more heavily on the inner portion of the pier than on the outer 4 in, for unless this is done the outer shell will take most of the load, and will be likely to bulge away from the core. A pier which supports a girder or column should have a cap-stone or iron plate of sufficient strength to distribute the pressure over the entire cross-section of the pier.

Walls faced with Stone, Terra-Cotta, or Cement Blocks. Brick walls faced with blocks or ashlar of any material should always have the backing laid in cement mortar or in cement-and-lime mortar, unless the backing is very thick, that is, 30 in or more. The aggregate thickness of the mortar joints in the backing is so much greater than in the facing, that any shrinkage or compression of the mortar tends to throw undue weight on the facing and to separate it from the backing. Veneering of any kind should be tied to the backing at least every 18 in in height. The New York Building Code (1906, Sections 28 and 29) requires that all bearing walls faced with bricks laid in running bond, and all walls faced with stone ashlar less than 8 in thick, shall be of such thickness as to make the wall independent of the facing conform to that required for unfaced walls. Ashlar 8 in thick and bonded into the backing may be counted as part of the thickness of the wall.

Grouting.† It is contended by persons having large experience in building that masonry carefully grouted, when the temperature is not lower than 40° F., will give the most efficient result. Many of the largest buildings in New York City have grouted walls. The Mersey docks and warehouses at Liverpool, England, one of the greatest pieces of masonry in the world, were grouted throughout. It should be stated, however, that there are many engineers and others who do not believe in grouting, claiming that the materials tend to separate and form layers.

Crushing Height of Brick and Stone. If we assume that the weight of brickwork is 120 lb per cu ft, and that it would commence to crush under 700 lb

* The manner in which brick piers fail is excellently shown by illustrations on page 79 of the Brickbuilder for May, 1896.

† See American Architect, July 21, 1887, page 11.

per sq in, then a wall of uniform thickness would have to be 840 ft high before the bottom courses would commence to crush from the weight of the brickwork above. Average sandstones, at 145 lb per cu ft, would require a column 5 950 ft high to crush the bottom stones, and an average granite, at 165 lb per cu ft, would require a column 10 470 ft high. The Merchants' shot-tower at Baltimore is 246 ft high, and its base sustains a pressure of 6½ tons per sq ft, the tons being long tons of 2 240 lb. The base of the granite pier of Saltash Bridge (by Brunel), of solid masonry to the height of 96 ft, and supporting the ends of two iron spans of 455 ft each, sustains 9½ tons per sq ft.

Stone Piers. Piers of good strong building stone laid in courses the full cross-sections of the piers, with the top and bottom courses bedded true and even, may be built to support very heavy loads. The height of such piers, however, should not exceed ten times the least lateral dimension, and when it exceeds eight times the thickness, the load should be reduced. The joints should not exceed ⅜ in in thickness and should be spread with 1 : 2 Portland-cement mortar, kept back 1 in from the face of the pier to prevent spalling of the edges. A test of the strength of a limestone pier 12 in square is described under Marbles and Limestones, in this chapter. Rubble-work should not be used for piers whose height exceeds five times the least dimension, or in which the latter is less than 20 in.

Records of Tests on the Crushing Resistance of Bricks. Table III gives the results of some tests on bricks, made under the direction of Mr. Kidder in behalf of the Massachusetts Charitable Mechanics' Association.

Table III. Ultimate and Cracking Strengths of Bricks

Kind of brick	Size of test-specimen	Area of face, sq in	Commenced to crack under lb per sq in	Net strength, lb per sq in
Philadelphia face-brick	Whole brick	33.7	4 303	6 062

New England pressed brick	Half brick	13.45	4 535	13 085
Average	....	....	4 764	12 490

The specimens were tested in the government testing-machine at Watertown, Mass., and great care was exercised to make the tests as perfect as possible. As the parallel plates between which the bricks are crushed are fixed in one position, it is necessary that each specimen tested should have perfectly parallel faces. The bricks which were tested were rubbed on a revolving bed until the top and bottom faces were perfectly true and parallel. The preparation of the bricks in this way required a great deal of time and expense; and it was so difficult to prepare some of the harder bricks that they had to be broken and only one-half of the brick prepared at a time.

The Philadelphia bricks used in these tests were obtained from a Boston dealer, and were fair samples of what is known in Boston as Philadelphia Face-Bricks. They were very soft bricks.

The Cambridge bricks were the common bricks, such as are made around Boston. They are about the same as the Eastern bricks.

The Boston Terra-Cotta Company's bricks were manufactured of a rather fine clay, and were such as are often used for face-bricks.

The New England pressed bricks were hydraulic-pressed bricks, and were almost as hard as iron.

From tests made on the same machine by the United States Government in 1884, the average strength of three (M. W. Sands) Cambridge, Mass., face-bricks was 13 925 lb, and of his common bricks, 18 337 lb per sq in, one brick developing the enormous strength of 22 351 lb per sq in. This was a very hard-burned brick. Three bricks of the Bay State (Mass.) manufacture showed an average strength of 11 400 lb per sq in. The New England bricks are among the hardest and strongest in the country, those in many parts of the West not having one-fourth the strength given above; so that in heavy buildings, where the strength of the bricks to be used is not known by actual tests, it is advisable to have the bricks tested. Ira O. Baker reported some tests on Illinois bricks, made on the 100 000-pound testing-machine at the University of Illinois in 1888 and 1889, which give for the crushing strength of soft bricks, 674 lb per sq in, for the average of three face-bricks, 3 070 lb per sq in, and for four paving-bricks, 9 775 lb per sq in. In nearly all makes of bricks it will be found that the face-bricks are not as strong as the common bricks.

Tests of the Strength of Brick Piers Laid with Various Mortars.* These tests were made for the purpose of testing the strength of brick piers laid up with different cement mortars, as compared with those laid up with ordinary mortar. The bricks used in the piers were procured at M. W. Sands's brickyard, Cambridge, Mass., and were good ordinary bricks. They were from the same lot as the samples of common bricks described above. The piers were 8 by 12 in in cross-section, and nine courses, or about 22½ in high, excepting the first, which was but eight courses high. They were built Nov. 29, 1881, in one of the storehouses at the United States Arsenal in Watertown, Mass. In order to have the two ends of the piers perfectly parallel surfaces, a coat of pure Portland cement, about ½ in thick, was put on the top of each pier and the foot was grouted in the same cement. On March 3, 1882, three months and five days later, the tops of the piers were dressed to plane surfaces at right-angles to the sides of the piers. On attempting to dress the lower ends of the piers, the cement grout peeled off, and it was necessary to remove it entirely and put on a layer of cement similar to that on the tops of the piers. This was allowed to harden for one month and sixteen days, when the piers were tested. At that time the piers were four months and twenty-six days old. As the piers were built in cold weather, the bricks were not wet. They were built by a skilled

* Made under the direction of F. E. Kidder.

bricklayer and the mortars were mixed under his superintendence. The tests were made with the government testing-machine at the Arsenal. The following table is arranged so as to show the result of these tests, and to afford a ready means of comparison of the strength of brickwork with different mortars. The piers generally failed by cracking longitudinally, and some of the bricks were crushed. The Portland cement used in these tests was made by Brooks, Shoobridge & Company, of England. Roman cement is a European natural cement, usually, although not always, containing a low percentage of magnesia. It sets rapidly, has about one-third the strength of true Portland cement and is much weakened by the addition of sand.

Table IV. Tests of Piers of Common Bricks Laid in Different Mortars

Piers 8 by 12 in in section, built of common bricks in common mortar	Ultimate strength of pier, lb	Pressure per sq in under which pier commenced to crack, lb	Ultimate strength, lb per sq in
Lime mortar	150 000	833	1 562
Lime mortar, 3 parts; Portland cement, 1 part	290 000	1 875	3 020
Lime mortar, 3 parts; Newark and Rosendale cements, 1 part	245 000	1 354	2 552
Lime mortar, 3 parts; Roman cement, 1 part	195 000	1 041	2 030
Portland cement, 1 part; sand, 2 parts	240 000	1 302	2 500
Newark and Rosendale cements, 1 part; sand, 2 parts	205 000	708	2 135
Roman cement, 1 part; sand, 2 parts	185 000	1 770	1 927

As the actual strength of brick piers is a very important consideration in building-construction, some tests, made by the United States Government at Watertown, Mass., and contained in the report of the tests made on the Government testing-machine for the year 1884, are given as being of much value. Three kinds of bricks were represented in the construction of the piers, and mortars of different composition, ranging in strength from lime mortar to neat Portland-cement mortar. The piers ranged in cross-section dimensions from 8 by 8 to 16 by 16 in, and in height from 16 in to 10 ft. They were tested at the age of from 18 to 24 months.

Table V gives the results obtained and memoranda regarding the size and character of the piers.

Table VI gives the results obtained from tests of the strength of brick piers made at the McGill University, Montreal, laboratories, in March, 1897.

Recent Tests of Brick Piers. Elaborate tests of brick piers, with valuable results,* were made in 1908 by A. N. Talbot and D. A. Abrams at the University of Illinois Experiment Station. Table VII is a summary of these results. The tests were made on sixteen brick piers, the lengths of which varied

* Published in Bulletin No. 27, University of Illinois Engineering Experiment Station, Sept. 29, 1908.

from 10 to 10½ ft. The lateral dimensions were 12½ by 12½ in. Two grades of bricks were used, an excellent class of building bricks and a soft grade selected as representative of inferior bricks. Different qualities of mortar and different grades of workmanship were employed.

Included in the same tests at the University of Illinois were compression-tests of single bricks, with the following average results. For hard, shale building bricks, bedded in plaster, crushing strength, flatwise, 10 700 lb per sq in; modulus of rupture, edgewise, 6-in span, 1 670 lb per sq in. For soft or underburned clay bricks, crushing strength, flatwise, 3 900 lb per sq in; modulus of rupture, 480 lb per sq in.

Tensional Strength of Brickwork. For the safe tensional strength of brickwork and other materials in footings, see Chapter II, page 179.

2. Strength of Terra-Cotta and Terra-Cotta Piers

General Properties of Terra-Cotta. The lightness of terra-cotta, combined with its great compressive strength, together with its durability and indestructibility by fire, water, frost, etc., renders it an especially valuable building material. Terra-cotta for building purposes, whether plain or ornamental, is generally made of hollow blocks formed with webs to give extra strength and keep the work true while drying. This is necessary because good, well-burned terra-cotta cannot safely be made more than about 1½ in thick, whereas, when required to bond with brickwork, it must be at least 4 in thick. When extra strength is needed, these hollow spaces are filled with concrete or brickwork, which greatly increases the crushing strength of the terra-cotta, although alone it is able to bear a very heavy weight. "A solid cubical block of terra-cotta has borne a crushing-stress of more than 500 tons."

Crushing Strength of Terra-Cotta Blocks. Some exhaustive experiments made by the Royal Institute of British Architects give the following results as the crushing strengths of terra-cotta blocks:

	Crushing weight per cu ft
Solid block of terra-cotta	523 tons
Hollow block of terra-cotta, unfilled	186 tons
Hollow block of terra-cotta, lightly made and unfilled	80 tons

Tests of terra-cotta manufactured by a New York Company, which were made at the Stevens Institute of Technology in April, 1888, gave the following results:

	Crushing weight per cu in		Crushing weight per cu ft
Terra-cotta block, 2-in square, red	6 840 lb	or	492 tons
Terra-cotta block, 2-in square, buff	6 236 lb	or	449 tons
Terra-cotta block, 2-in square, gray	5 126 lb	or	369 tons

In tests for the New York Building Department, made at Columbia University, dense terra-cotta blocks developed a net crushing strength of 4 721 lb per sq in or 340 tons per sq ft, and semiporous, 2 168 lb per sq in or 156 tons per sq ft, these results being in each case the averages of a series of tests. (See page 816.)

From these results, the writer would place the safe working strength of terra-cotta blocks in the wall at 5 tons per sq ft when unfilled, and 10 tons per sq ft when filled solid with brickwork or concrete.

Tests of Terra-Cotta Piers. Tests * of terra-cotta block piers were made about the same time (January, 1907, and January, 1908) that the brick piers referred to in Table VII were made. The tests were made on terra-cotta piers, the lengths of which varied from 9 ft 9 in to 12 ft 7¾ in. The lateral dimensions varied from 8½ by 8½ in to 17½ by 17½ in. "The piers were built and tested in two lots, an interval of about one year separating the times of making the tests. The two lots of piers were built of blocks which came in different shipments. The cement used was the same brand in both years, although the lots

Table VIII. Tests of Terra-Cotta Piers, Made at the University of Illinois

The amounts given are average values. The table gives results of tests of piers of second shipment, except for the concave-end blocks. The piers recorded in this table were all 12½ by 12½ in by 9¾ ft.

Characteristics of piers	Average unit load lb per sq in	Ratio of strength of pier to strength of block, gross area	Ratio of strength of pier to strength of first of series	Crushing strength of 6-in mortar-cubes lb per sq in.	Ratio of strength of pier to strength of cubes

* Estimated. † Blocks of good quality, but underburned.

were different. The terra-cotta block piers were generally made in sets of two. Each set was constructed and loaded similarly. Three of the piers were laid up hurriedly (poorly laid); the remainder were built with the usual care given to such work. The load was applied to the piers in different ways, although generally applied continuously to failure." Some piers were loaded eccentrically to failure and one was loaded both concentrically and eccentrically, but the additional eccentric load was not sufficient to cause failure.

* See Bulletin No. 27, University of Illinois Engineering Experiment Station, Sept. 29, 1908.

Comparison of Results of Tests of Brick and Terra-Cotta Piers. In the tests summarized in Tables VII and VIII, "both the brick piers and the terra-cotta block piers gave high strengths in all cases where strong mortar and care in building were used. The effect of the strength of the mortar was apparent in the carrying capacity developed in the piers, smaller loads being indicated for piers built with 1 : 5 Portland-cement mortar than for those with 1 : 3 Portland-cement mortar, and still smaller loads for those with 1 : 2 lime mortar. The effect of the quality of the bricks is shown in the piers made with inferior bricks, these piers carrying only 31% as much as piers built with the better grade of bricks. In the case of the terra-cotta piers, the blocks which were culled out as somewhat inferior gave a pier-strength which was perhaps 30% less than the piers built with superior blocks. The effect of the attempt to represent hurried or careless workmanship in two brick piers and in three terra-cotta block piers was a loss in strength of about 15% and 25% respectively.

"In the well-built brick piers, concentrically loaded, the ratio of strength of pier to compressive strength of individual brick ranged from 31 to 37%, and in the underburned clay-brick pier the ratio was 27%. In the terra-cotta block piers, concentrically loaded, the ratio of strength of pier to that of individual block was 74% (an incompleted test) and 83, 85 and 89% for the others. The higher ratio found for the terra-cotta block piers than for brick piers suggests that the ability of individual pieces to resist transverse forces is an element in the strength of the completed pier; and this suggestion may have an important bearing on the advantageous size of the component blocks which may be used in a compression-piece where great strength is required.

"The strength of the pier is greater than that of the mortar-cubes in both brick and terra-cotta block piers, except the soft-brick piers, which had bricks of low compressive strength. Both the strength of the individual bricks or blocks and the strength of the mortar affect the resistance of the pier, and the relative effect of the two depends upon the character of the materials. It is evident, however, that the better the individual piece the more important it is to have a mortar of high resisting strength.

"The results obtained in applying the loads eccentrically were found to agree very well with those obtained from ordinary analysis.

"The quality of workmanship in laying up such columns has an important bearing upon the resisting strength. The work of building piers, however, is not difficult and requires only ordinary care. Full joints and an even bearing are important, and the ordinary workman ought to be able to construct piers of great strength. In the tests made on piers intended to represent poor or careless workmanship, the decrease in strength was not as much as anticipated. However, it must be understood that careful and trustworthy work is essential and that a few poor joints will materially reduce the strength of the structure. Wherever good material and good workmanship are insured the strength of masonry of this kind may be utilized with advantage."

Strength of Terra-Cotta Brackets or Consoles. A cornice-modillion made by the Northwestern Terra-Cotta Company, 11½ in high at the wall-line, 8 in wide on the face, and with a projection of 2 ft, was built into a wall and the upper surface loaded with 2 tons of pig iron without any effect upon the modillion. Another bracket, 5½ in high, 6 in wide and with a 14-in projection, made in the East, broke at the wall-line under 2 650 lb, while a duplicate of it sustained 2 400 lb for one month without breaking.*

The Weight of Terra-Cotta. The weight of terra-cotta in solid blocks is 120 or 122 lb per cu ft. When made in hollow blocks 1½ in thick the weight

* See The Brickbuilder, Vol. 7, page 142.

varies from 65 to 85 lb per cu ft, the smaller pieces weighing the most. For pieces 12 by 18 in or larger on the face, 70 lb per cu ft will probably be a fair average. The tables in the manufacturers' catalogues give the various bearing-areas, weights per square foot, thicknesses of parts, sizes of blocks, etc., for porous and semiporous blocks for all purposes.

3. Crushing Strength of Building Stones

(1) Sandstones

Longmeadow, Mass., Stone.* Reddish-brown sandstone, two blocks about 4 by 4 in in cross-section and 8 in in height.

Block No. 1 commenced to crack at 10 333 lb per sq in, and flew from the machine in fragments at 13 596 lb per sq in.

Block No. 2 commenced to crack at 3 012 lb per sq in and failed completely at 9 121 lb per sq in.

Sandstone from Norcross Brothers' Quarries, East Longmeadow, Mass., Soft Saulsbury Stone.* Block No. 1, 4 by 4 by 8 in high, commenced to crack at 8 250 lb and failed at 8 812 lb per sq in.

Block No. 2, 4 by 4 by 8 in high, commenced to crack at 6 500 lb and failed at 8 092 lb per sq in.

Hard Saulsbury Stone.* Block No. 1, 4 by 4 by 8 in high (about), commenced to crack at 12 716 lb and failed at 13 520 lb per sq in.

Block No. 2, same size as No. 1, commenced to crack at 13 953 lb and failed at 14 650 lb per sq in.

Kibbe Stone.* Block No. 1, 6 by 6 by 6 in, commenced to crack at 12 590 lb and failed at 12 619 lb per sq in.

Block No. 2, same size as No. 1, commenced to crack at 12 185 lb and failed at 12 874 lb per sq in.

Brown Stone from the Shaler & Hall Quarry Company, Portland, Conn.† The results of the tests are as follows:

Table IX. Crushing Strength of Brown Sandstone

Dimensions: Height, in	Dimensions: Compressed, surface, in		Sectional area, sq in	First crack, lb	Ultimate strength, lb per sq in	Classification
2.50	2.50	2.45	6.13	84 800	13 980	1st quality
2.50	2.48	2.47	6.13	81 700	13 330	1st quality
2.98	3.00	2.95	8.85	123 200	13 920	2d quality
2.95	2.98	2.97	8.85	122 000	15 020	3d quality
2.51	2.55	2.53	6.45	63 850	9 900	Bridge
2.48	2.48	2.52	6.25	58 340	9 330	Bridge

Brown Stone from the Middlesex Quarry Company, Portland, Conn.‡ Four nearly cubical blocks, about 1½ in square. Pressure per square inch at time of failure: No. 1, 10 928 lb; No. 2, 10 322 lb; No. 3, 8 252 lb and No. 4, 6 322 lb.

* These tests were made with the United States testing-machines at Watertown Arsenal, Mass.

† From tests made by Colt's Patent Fire-arms Manufacturing Company.

‡ These tests were made with the United States testing-machines at Watertown Arsenal, Mass.

Red Sandstone * from Greenlee & Son's Quarries at Manitou, Col. One specimen failed at 11 000 lb per sq in; weight, 140 lb per cu ft.

Light-Red Laminated Sandstone,† from St. Vrain Cañon, Col., a very hard stone, excellent for walks and foundations. Crushing strength on bed, 11 505 lb per sq in; weight, 150 lb per cu ft.

Gray Sandstone † (free-working) from Trinidad, Col. Crushing strength, 10 000 lb per sq in; weight, 145 lb per cu ft.

Gray Sandstone † from Fort Collins, Col. (laminated and similar in quality to the St. Vrain stone). Crushing strength on bed, 11 700 lb per sq in; weight, 140 lb per cu ft. One ton of this stone measures just a perch in the wall.

(2) Granite

Red Granite † from Platte Cañon, Col. Crushing strength per square inch, 14 600 lb; weight per cubic foot, 164 lb.

(3) Lava Stones

Lava Stone from the Kerr Quarries, near Salida, Col. Four cubical blocks.‡ The results of the tests are as follows:

Table X. Crushing Strength of Lava Stone

Dimensions			Sectional area	First crack	Ultimate strength	
Height in	Compressed surface in		sq in	lb	lb	lb per sq in
4.00	4.00	4.00	16.00	165 900	165 000	10 369
4.00	4.00	4.00	16.00	174 100	174 100	10 881
2.00	2.00	1.99	3.98	36 400	37 100	9 322
1.99	1.99	1.99	3.96	38 200	38 200	9 646

Lava Stone,‡ Curry's Quarry, Douglas County, Col. Crushing strength, 10 675 lb per sq in; weight, 119 lb per cu ft. Experience has shown that this stone is not suitable for piers, or where any great strength is required, as it cracks very easily.

(4) Marble and Limestone

White marble quarried at Sutherland Falls, Vt. Two cubical blocks about 6 in square.§

Block No. 1 commenced to crack at 9 750 lb per sq in and failed suddenly at 11 250 lb per sq in.

Block No. 2 did not crack until it suddenly gave way at 10 243 lb per sq in.

Test of a Limestone Pier. A pier of Lemont limestone, 1 sq ft in cross-section and 9 ft in height, composed of seven stones with bearing surfaces planed perfectly true and parallel to the natural bed and the joints washed with a thin grout of the best English Portland cement, was tested at the Watertown Arsenal for William Sooy Smith, and only commenced to crack when the full power of the machine, 400 tons, was exerted.

* These tests were made with the United States testing-machines at Watertown Arsenal, Mass.

† From tests made for the Board of Capitol Managers of Colorado by State Engineer E. S. Nettleton, in 1885, on 2-in cubes.

‡ From tests made by the Denver Society of Civil Engineers, in 1884, also on 2-in cubes.

§ Tested at the United States Arsenal, Watertown, Mass.

(5) Bricks and Various Stones

Table XI gives the crushing strength of various kinds of bricks and building stones, the pressure being normal to the plane of the bed.

Table XI. Crushing Strength of Brick and Stone *
Pressure at right-angles to bed

Kind of brick or stone	Crushing strength, lb per sq in
Bricks:	
Common, Massachusetts	10 000
Common, St. Louis, Mo.	6 417

* For more complete tables of the strength, weight and composition of building stones, see new data, tables, etc. by Professor Thomas Nolan in Kidder's Building Construction and Superintendence, Part I, Masons' Work.

† This stone should not be set on edge.

(6) Additional Data on the Strength of Building Stones

Average Data for Building Stones of Good Quality. The following average relative values* are given by R. P. Miller.† SANDSTONE: weight, 150 lb per cu ft; specific gravity, 2.40; crushing strength, 8 000 lb per sq in; shearing strength, 1 500 lb per sq in; modulus of rupture, 1 200 lb per sq in; modulus of elasticity, 3 000 000 lb per sq in. GRANITE: weight, 170; specific gravity, 2.72; crushing strength, 15 000; shearing strength, 2 000; modulus of rupture, 1 500; modulus of elasticity, 7 000 000. LIMESTONE: weight, 170; specific gravity, 2.72; crushing strength, 6 000; shearing strength, 1 000; modulus of rupture, 1 200; modulus of elasticity, 7 000 000. MARBLE: weight, 170; specific gravity, 2.72; crushing strength, 10 000; shearing strength, 1 400; modulus of rupture, 1 400; modulus of elasticity, 8 000 000. SLATE: weight, 175; specific gravity, 2.80; crushing strength, 15 000; modulus of rupture, 8 500; modulus of elasticity, 14 000 000. TRAP-ROCK: weight, 185; specific gravity, 2.96; crushing strength, 20 000.

The following average relative values are given by A. I. Frye.‡ They are the results of tests made on small cubes of the materials. SANDSTONE: crushing strength, 9 000 lb per sq in; GRANITE and GNEISS: crushing strength, 17 733 lb per sq in. LIMESTONES and MARBLES: crushing strength, 14 445 lb per sq in. SLATE: crushing strength, 10 000; ultimate tensional strength, 3 000; modulus of rupture, 5 000 lb per sq in.

When stones are not tested, Frye recommends the following average values for ultimate strengths to be used in determining the safe stresses. SANDSTONE: crushing strength, 5 000; ultimate tensional strength, 150; modulus of rupture, 1 200 lb per sq in. GRANITE and GNEISS: crushing strength, 12 000; modulus of rupture, 1 600 lb per sq in. LIMESTONES and MARBLES: crushing strength, 8 000; ultimate tensional strength, 800; modulus of rupture, 1 500 lb per sq in.

The following working unit stresses in pounds per square inch for stone slabs or single blocks of stone are recommended by W. J. Douglass.§ SANDSTONE: compression, 700; tension (direct and flexural), 75; shear, 150. GRANITE, SYENITE and GNEISS: compression for hard, 1 500; for medium, 1 200; for soft, 1 000; tension (direct and flexural), 150; shear, 200. LIMESTONE: compression for hard, 1 000; for medium, 800; for soft, 700; tension (direct and flexural), 125; shear, 150. MARBLE: compression for hard, 900; for soft, 700; tension (direct and flexural), 125; shear, 150. BLUESTONE FLAGGING: compression, 1 500; tension (direct and flexural), 200.

4. Compressive Strength of Mortars and Concretes

The Compressive Strength of Lime Mortar. The crushing strength of common lime mortar, six months old and composed of 1 part lime to 6 parts sand by measure, varies from 150 to 300 lb per sq in or from 10.8 to 21.6 tons per sq ft. Lime mortar alone should never be used where any but moderate loads are to bear upon the work, nor where the full loading is to be applied before the mortar has had time to harden.

* The values in all cases are as follows: weight, in lb per cu ft; strength, modulus of rupture and modulus of elasticity, in lb per sq in.

† American Civil Engineers' Pocket Book (1912), page 357.

‡ Civil Engineers' Pocket-Book (1913), page 511.

§ American Civil Engineers' Pocket Book (1912), page 575.

The Compressive Strength of Natural-Cement Mortar. The crushing strength * of natural-cement mortar, neat, averaged, for 7 days, 2 010; for 28 days, 2 689; for 3 months, 3 646; and for 6 months, 5 052 lb per sq in. When mixed with 2 parts of standard quartz sand, the mortar averaged in crushing strength, for 7 days, 940; for 28 days, 1 390; for 3 months, 1 730; and for 6 months, 2 012 lb per sq in. For 2 years, an additional increase of 18% and 6% may be assumed for the neat and sanded mortars, respectively, of natural cement.

The Compressive Strength of Portland-Cement Mortar. The crushing strength * of Portland-cement mortar, neat, averaged, for 7 days, 5 915; for 28 days, 7 041; for 3 months, 7 347; and for 6 months, 9 760 lb per sq in. When mixed with 3 parts of standard quartz sand, the mortar averaged, in crushing strength, for 7 days, 941; for 28 days, 1 290; for 3 months, 1 490; and for 6 months, 1 529 lb per sq in. When mixed with 3 parts of Ottawa sand, the mortar averaged, in crushing strength, for 7 days, 1 199; for 28 days, 1 796; for 3 months, 1 887; and for 6 months, 2 181 lb per sq in. For 2 years, an additional increase of about 16% and 18% may be assumed for the neat and sanded mortars, respectively, of Portland cement.

Relation of Compressive to Tensile Strength of Mortars. While it may be stated as a very general guide that the compressive strength of hydraulic-cement mortars is from six to ten times the tensile strength, these ratios are variable and cannot be used as a reliable basis for calculations. The tensile strength of Portland-cement mortars, under normal conditions, increases rapidly during the first few days, the rate of change gradually falling off. In 7 days the tensile strength is generally from one-half to two-thirds of the ultimate strength, which is practically reached in 2 or 3 months. The compressive strength, however, continues to increase with age and the rate of increase varies according to a somewhat different law.

The Compressive Strength of Concrete. There are many reasons for the variations in the values of the compressive strength of concrete and the principal factors are (1) the quality of the cement, (2) the size and character of the aggregates, (3) the quantity of the cement to a unit volume of the concrete, (4) the manner of mixing, (5) the density of the mixture, (6) the conditions under which it seasons, and (7) its age; and of these various conditions affecting the determination of the compressive strength the most important are generally the proportions of the different ingredients of the mixture and its age. Although tables of average values of ultimate crushing strengths of concrete are published and are of general value, they may be misleading unless considered with caution. In important operations it is advisable to have the concrete tested and to adjust by trial the character and proportions of the ingredients until the required strength is obtained.

Form of Specimen for Compression-Tests. For compression-tests of concrete in general, 4 to 12-in cubes of the mixture have been the standard forms of test-specimens; but since the advent of reinforced-concrete construction and the growth of the importance of determining the elastic properties of concrete, it has been found that a cylindrical test-specimen gives more definite results than a cube. A common shape of such cylinder is one in which the height is about three times the diameter, and the cylinders are not less than 6 by 18 in. It is found that the compressive strengths of these cylinders of concrete are from 10 to 15% less than those of the cubes, but for cylinders of

* From compression-tests made by W. P. Taylor on cylindrical specimens 1 in in height, about 1⅛ in in diameter and 1 sq in in cross-section.

still greater slenderness the compressive strengths remain about constant for heights up to about seven diameters.

Compression-Tests on Concrete Cubes. From some tests made in 1899 for the Boston Elevated Railway Company at the Watertown Arsenal, on 12-in cubes of concrete made with five brands of Portland cement, coarse, sharp sand and broken stone up to 2½-in size, having 49.5% voids, the following average values of the compressive strengths were obtained:

Table XII. Compression-Tests on Concrete Cubes

Mixtures	7 days lb per sq in	1 month lb per sq in	3 months lb per sq in	6 months lb per sq in
1 : 2 : 4	1 560	2 400	2 900	3 820
1 : 3 : 6	1 310	2 160	2 520	3 090

Compression-Tests on Concrete-Cylinders. For cylindrical test-specimens of concrete, made under reasonably good conditions as to character of materials and care in mixing, an average compressive strength of about 2 000 lb per sq in is usually developed in a 1 : 2 : 4 Portland-cement concrete in from 1 to 2 months; and of about 1 600 lb per sq in in a 1 : 3 : 6 mixture. When the conditions are unusually favorable somewhat higher values than these are obtained, but when the materials and workmanship are poor the ultimate compressive stresses are lower.

Increase in Compressive Strength of Portland-Cement Concrete. In regard to the increase of compressive strength of Portland-cement concrete with age, tests show that the ultimate compressive strength is nearly reached in 60 days, at which time the strength varies from 80 to 90% of its value in 1 year's time.

Ultimate Strengths of Natural-Cement Concrete. For natural-cement concrete, the ultimate compressive, tensile and shearing strengths and the modulus of rupture may be taken at about one-half the corresponding values for Portland-cement concrete, unless natural cements of known and tested values are employed.

Strength of Unreinforced Concrete Columns. Short concrete columns, of lengths up to 10 or 15 diameters, develop a crushing strength of from 10 to

Table XIII. Compression-Tests on Unreinforced Concrete Columns

Kind of concrete	Average age days	Average ultimate compressive stress lb per sq in
1 : 1 : 2	60	3 600*
1 : 1½ : 3	60	2 270
1 : 2 : 4	60	1 600
1 : 2½ : 5	60	1 200
1 : 3 : 6	60	935
1 : 3½ : 7	60	745
1 : 4 : 8	60	600

* This value was estimated as it was beyond the range of the tests.

20% less than that for short prismatic or cylindrical specimens. In Table XIII are the results obtained by A. N. Talbot * on short, round, unreinforced stone-concrete columns, 12 in in diameter and 10 ft in length. A wet-mixture concrete was used, of the different proportions shown, the forms were removed after 10 days and the columns were tested through 60 days.

The values given in the table were deduced from the straight-line formula

$$\text{Ultimate compressive strength, lb per sq in} = \frac{12\,000}{S_a + S_t} - 400$$

in which formula

S_a = the ratio of sand to cement
S_t = the ratio of stone to cement

For example, in the 1 : 3 : 6 mixture, $S_a = 3$ and $S_t = 6$

Crushing Strength of Concrete Affected by Area of Bearing Surface. Professor Hool states † that if a load is applied over the central part, only, of the bearing surface of a concrete test-specimen in compression, the unit load will be greater than if it is applied over the entire surface; and this is due to the fact that the outer parts tend to assist the inner part to resist the stress. This was shown by tests made on some of the 12-in concrete cubes used in the tests made for the Boston Elevated Railway Company and referred to in the preceding paragraphs. Thirty-six of these concrete cubes were crushed by applying the load over the entire upper bearing-surface of 144 sq in and an equal number of similar concrete cubes were then crushed by applying the stress over a smaller area, 10 by 10 in, or 100 sq in. After this, the cubes of a third set were crushed by the application of the stress over the still smaller area, 8 by 8¼ in, or 66 sq in. The tests of the second set gave unit crushing strengths 12% higher than the first, and those of the third set unit crushing strengths 28% higher than the first.

Working Stress for Bearing on Concrete. "When compression is applied to a surface of concrete of at least twice the loaded area, a stress of 32.5% of the compressive strength may be allowed."‡

Working Stress for Axial Compression on Concrete. "For concentric compression on a plain concrete column or pier, the length of which does not exceed 12 diameters, 22.5 % of the compressive strength may be allowed." * (For the strength of reinforced-concrete columns, see Chapter XXIV, page 945.)

Recommended Ultimate Compressive Strengths of Portland-Cement Concrete.‡ Table XIV, of ultimate compressive strengths of concrete of different mixtures gives the values recommended by the American Society for Testing Materials, even though occasional tests show higher results. The values given are recommended as the maximum ultimate unit compressive strengths that should be used in design and on which the permissible working stresses should be based as a proper percentage of the same. The report referred to states, also, that "in selecting the permissible working stresses to be allowed on concrete, we should be guided by the working stresses usually allowed for other materials of construction, so that all structures of the same class, but composed of different materials, may have approximately the same degree of safety." (For working stresses for concretes, masonry, etc., see this chapter, pages 265 to 276.)

* See University of Illinois Bulletin, No. 20, 1907, and Engineering News, Sept. 26, 1907.

† See Reinforced Concrete Construction, Vol I., page 18, by George A. Hool.

‡ Report of Committee on Concrete and Reinforced Concrete, of the American Society for Testing Materials, Nov. 20, 1912.

Table XIV. Ultimate Compressive Strengths of Different Mixtures of Portland-Cement Concretes

Aggregates	Mixtures				
	1 : 1 : 2 lb per sq in	1 : 1½ : 3 lb per sq in	1 : 2 : 4 lb per sq in	1 : 2½ : 5 lb per sq in	1 : 3 : 6 lb per sq in
Granite, trap-rock	3 300	2 800	2 200	1 800	1 400
Gravel, hard limestone and hard sandstone	3 000	2 500	2 000	1 600	1 300
Soft limestone and sandstone	2 200	1 800	1 500	1 200	1 000
Cinders	800	700	600	500	400

Effect of Consistency on the Crushing Strength of Concrete. Concrete that is mixed fairly dry and tamped until the moisture is brought to the surface, develops a somewhat greater compressive strength than concrete mixed with more water. From a large number of tests * average compressive strengths of wet, plastic and dry concretes were determined. The age of the concrete was 1 year and 8 months, and five brands of cements were used. The mean compressive strengths were, for the wet concrete, 2 130; for the plastic, 2 200; and for the dry, 2 350 lb per sq in.

In another series of tests † greater differences appeared. At the age of 1 month the mean compressive strengths in pounds per square inch were, for the wet concrete: granite, 3 155; gravel, 2 300; limestone, 4 195. For the medium concrete: granite, 4 090; gravel, 3 545; limestone, 2 975. For the damp concrete: granite, 4 520; gravel, 4 610; limestone, 4 365. At the end of 3 months the values for the granite aggregates were, for the wet concrete, 4 755; for the medium, 4 990; and for the damp, 5 445.

Effect of Size of Stone on the Compressive Strength of Concretes. It may be stated, generally, that the use of stones of a maximum size consistent with convenience generally results in a maximum compressive strength in the concrete. Stones of the larger sizes are generally more uniformly graded than the smaller stones, and consequently grade better with the sand and give greater strength. From tests ‡ made by W. B. Fuller, the average compressive strengths, at 140 days, of 1 : 9 concrete, were, for maximum size of stone ½ in, 1 000 lb per sq in; for 1-in stone, 1 150 lb per sq in; and for 2¼-in stone, 1 400 lb per sq in.

Comparison of Compressive Strengths of Gravel and Stone Concretes. Concretes made with broken stone have, generally, a somewhat greater compressive strength than those made with gravel. From tests made by E. Candlot, the average compressive strength at 30 and 180 days, of concrete made with 1½-in maximum-size broken stone, was 20% greater than that of concrete made of gravel of about the same size, the percentage of voids being nearly the same, 40% voids for the gravel and 47.4% voids for the broken stone. The average difference at 12 months, however, was reduced to 9%.

‡ See Trans. Am. Soc. C. E., Vol. 59, 1907.

Effect of the Strength of the Aggregate on the Compressive Strength of Concretes. The compressive strength of trap-rocks, granites and most limestones is relatively so great that it cannot reduce the strength of the concrete itself. Some sandstones, however, have a much lower average compressive strength, and if they are friable and soft may lower relatively the final strength of the concrete. A concrete of low strength results from using cinders for the aggregate

CHAPTER VI

FORCES AND MOMENTS

By

MALVERD A. HOWE

PROFESSOR OF CIVIL ENGINEERING, ROSE POLYTECHNIC INSTITUTE

1. Composition and Resolution of Forces

Composition and Resolution of Forces. Imagine a round ball placed on a plane, frictionless surface at A (Fig. 1), the surface being perfectly level, so that the ball has no tendency to move until some force is applied to it. If, now, the force, P, is applied to the ball in the direction indicated by the arrow, the ball will move in that direction. If, instead of one force only, two forces, P and P_1, are applied to the ball, it will not move in the direction of either of the forces, but will move in the direction of the RESULTANT of these forces, or in the direction Ab. If the magnitudes of the forces P and P_1 are indicated by the lengths of the lines, then, if we complete the parallelogram $ABDC$, the diagonal DA represents the direction and magnitude of a single force which has the same effect on the ball as that resulting from the two forces P and P_1. If, in addition to the two forces P and P_1, the third force, P_2, is applied, the ball will move in the direction of the resultant of all three forces, and this resultant is obtained by completing the parallelogram $ADEF$, of which the resultant DA and the third force P_2 are two adjacent sides. The diagonal R of this second parallelogram is the resultant of all three forces, and the ball will move in the direction Ae. In the same way the resultant of any number of forces may be found. Again, suppose a ball, whose weight is indicated by the length of the line W (Fig. 2), is suspended by two inclined cords. What are the magnitudes of the pulls or stresses which are developed in the cords and which keep the ball suspended at the point A? This is the converse of the last case. Instead of finding the diagonal or the resultant, the diagonal, which is the line W, is given, and the sides of the parallelogram are to be found. To find these the lines representing the directions of P and P_1 are prolonged and from B lines parallel to them are drawn to complete the parallelogram. Then CA is the required magnitude of the stress in cord P, and BC of that in cord P_1. Thus one force may have the same effect as many, or many the same effect as one.

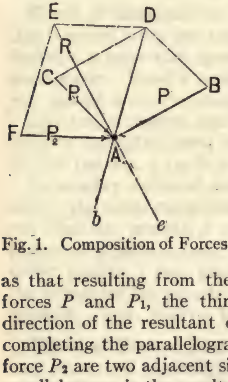

Fig. 1. Composition of Forces

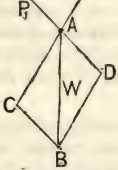

Fig. 2. Resolution of Forces

Forces Represented by Straight Lines. In considering the action of forces, it is convenient to represent them graphically by straight lines with arrowheads, as in Fig. 3. The length of the line, if drawn to a scale of pounds, represents the MAGNITUDE OF THE FORCE in pounds; the position of the line indicates

its LINE OF ACTION; the arrow-head indicates its SENSE or the direction in which it acts; and the point A its POINT OF APPLICATION. Thus the magnitude, direction and point of application are indicated and the force is completely represented.

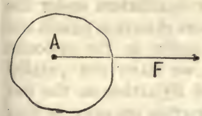

Fig. 3. Force Represented by a Straight Line

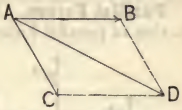

Fig. 4. Parallelogram of Forces

Parallelogram of Forces. If two forces applied at one point are represented in magnitude and direction by two straight lines inclined to each other, their resultant is the diagonal of the PARALLELOGRAM formed on those lines. Thus, if the lines AB and AC (Fig. 4) represent two forces acting at a point A, to find the force which will have the same effect as the two forces, the parallelogram $ABDC$ is completed and the diagonal AD drawn. This line represents the RESULTANT of the two forces. When the two given forces act at right-angles to each other, the magnitude of the resultant is equal to the square root of the sum of the squares of the magnitudes of the other two forces.

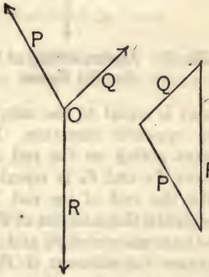

Fig. 5. Triangle of Forces

Triangle of Forces. If three forces acting at a point are represented in magnitude and direction by the sides of a TRIANGLE taken in order, they are in equilibrium. Let P, Q and R (Fig. 5) represent three forces acting at the point O. If a triangle can be drawn, like that shown at the right in Fig. 5, having sides respectively parallel to the directions of the forces and taken in the same order, the forces are in equilibrium. If such a triangle cannot be drawn, the forces are not in equilibrium.

The Polygon of Forces. If any number of forces acting at a point can be represented in magnitude and direction by the sides of a POLYGON taken in order, they are in equilibrium. This follows directly from the preceding theorem.

2. Moments of Forces

Moments. In considering the stability of structures and the strength of materials, we are often obliged to take into consideration the moments of the forces acting on a structure or on some part of a structure; and a knowledge of the general PRINCIPLES OF MOMENTS is essential to the proper understanding of these subjects. When we speak of the MOMENT OF A FORCE, we must have in mind some fixed point or line with respect to which the moment is taken. The moment of a force with respect to any given point, or CENTER OF MOMENTS, is the product of the magnitude of the force and the perpendicular distance from the point to the LINE OF ACTION of the force; or, in other words, the moment of a force is the product of the magnitude of the force by the ARM with which it acts. Thus if we have the force F (Fig. 6), and wish to determine its moment with respect to the point P, we determine the perpendicular distance Pa, between the point and the line of action of the force, and multiply it by the magnitude of the force. For example, if the magnitude

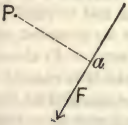

Fig. 6. Moment of a Force

of the force F is 500 lb and the distance Pa is 2 in, the moment of the force with respect to the point P is 500 lb × 2 in = 1 000 in-lb.*

Parallel Forces. If any body is in a state of rest or equilibrium under the action of parallel forces, the sum of the forces acting in one direction equals the sum of the forces acting in the opposite direction. Thus if we have the parallel forces P^1, P^2, P^3 and P^4 acting on the rod AB (Fig. 7), in a direction opposite to that of the forces P_1, P_2 and P_3, then, if the rod is in equilibrium, the sum of the forces P^1, P^2, P^3 and P^4 must equal the sum of the forces P_1, P_2 and P_3.

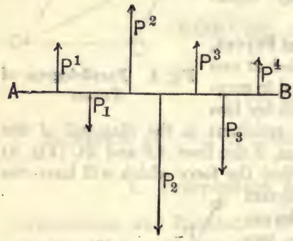

Fig. 7. Algebraic Sum of Unlike Parallel Forces

Parallel Forces Opposite in Character. If any number of parallel forces, not all acting in the same direction, act on a body, if the body is in equilibrium, the sum of the moments of the forces tending to turn the body in one direction about any given point is equal to the sum of the moments of the forces tending to turn it in the opposite direction. Let F_1, F_2 and F_3 (Fig. 8) represent three parallel forces acting on the rod AB. If the rod is in equilibrium, the sum of the forces F_2 and F_3 is equal to F_1. Also, if we take the end of the rod, A, for the center of moments, the moment of F_1 is equal to the sum of the moments of F_2 and F_3 about that point, because the moment of F_1 measures the tendency to turn the rod CLOCKWISE, and the sum of the moments of F_2 and F_3 measure the tendency to turn the rod CONTRA-CLOCKWISE, and there is no more tendency to turn the rod one way than the other. For example, let the magnitude of forces F_2, F_3 each be represented by 5 force-units, the distance Aa by 2 length-units and the distance AB by 4 length-units. The magnitude of the force F_1 must equal the sum of the magnitudes of the forces F_2 and F_3, or 10 force-units, and its moment with respect to any point in the plane of the forces must equal the sum of the moments of F_2 and F_3 with respect to the same point. If we take A as the center of moments, the moment of $F_3 = 5 \times 2 = 10$, and of $F_2 = 5 \times 4 = 20$. Their sum equals 30; hence the moment of F_1 must be 30. Dividing the moment 30 by the force $F_1 = 10$ force-units, we have for the arm, 3 length-units; or the force F_1 must act at a distance of 3 units from A to keep the rod in equilibrium. If we take b as the center of moments, the force F_1 has no moment, as the length of its lever-arm is zero; and, for equilibrium, the moment of F_2 about b must equal the moment of F_3 about the same point; or, as in this case the magnitudes of the forces F_2 and F_3 are equal, they must both be applied at the same distance from b, showing that b must be half-way between a and B, as was demonstrated before.

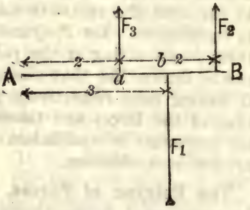

Fig. 8. Algebraic Sum of Moments of Unlike Parallel Forces

Three Parallel Forces. THE PRINCIPLE OF THE LEVER. This principle is based upon the two preceding propositions and is of great importance and con-

* The expressions POUND-FEET and POUND-INCHES are often given to these products to distinguish them from FOOT-POUNDS and INCH-POUNDS, by which WORK and ENERGY are measured.

venience. If a body is in equilibrium under the action of three parallel forces acting in the same plane, each force is proportional to the normal distance between the other two. Thus, if, as in Figs. 9, 10 and 11, three forces, P_1, P_2 and

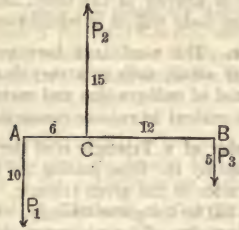

Fig. 9. Principle of the Lever

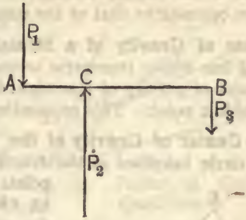

Fig. 10. Principle of the Lever

P_3, act on the rod AB, in order that it may be in equilibrium, the following relations must obtain between the magnitudes of the forces and the distances between their points of application;

$$\frac{P_1}{CB} : \frac{P_2}{AB} : \frac{P_3}{AC}$$

or

$$P_1 : P_2 : P_3 :: CB : AB : AC$$

This is the case of the COMMON LEVER and shows the method of determining what weight a given lever will raise. The proportion is also true for any arrangement of the forces (as shown in Figs. 9, 10 and 11), provided, of course, the forces are lettered in the order shown in the figures.

For example, let the distance AC be 6 in and the distance CB be 12 in. If a weight of 500 lb is applied at the point B, how much will it raise at the other end and what support will be required at C (Fig. 10)?

Applying the rule just given, we have the proportion:

$$P_3 : P_1 :: AC : CB \quad \text{or} \quad 500 : P_1 :: 6 : 12$$

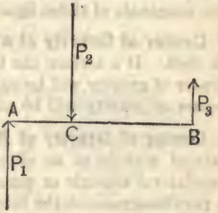

Fig. 11. Principle of the Lever

Hence $P_1 = 1\,000$ lb; or 500 lb applied at B will lift 1 000 lb resting on or suspended at A. The supporting force at C must, by the principles of PARALLEL FORCES IN EQUILIBRIUM, be equal to the sum of the forces P_1 and P_3, or 1 500 lb in this case.

3. Center of Gravity

General Principles. The LINES OF ACTION of the force of gravity converge towards the center of the earth; but the distance of the center of the earth from the bodies which we have occasion to consider, compared with the size of those bodies, is so great, that we may consider the lines of action of the forces as parallel. The number of the forces of gravity acting upon a body may be considered as equal to the number of particles composing the body. The CENTER OF GRAVITY of a body may be defined as the point through which the resultant of the parallel forces of gravity, acting upon the body, passes for every position of the body. If a body is supported at its center of gravity and turned about

that point, it will remain in equilibrium in all positions. The resultant of the parallel forces of gravity acting upon a body is obviously equal to the WEIGHT OF THE BODY; and if a force, equal in magnitude to the resultant, is applied, acting in a line passing through the center of gravity of the body, and in a direction opposite to that of the resultant, the body will be in equilibrium.

Center of Gravity of a Straight Line. The word LINE here means a material line whose transverse section is very small, such as a very fine wire. The center of gravity of a straight line or rod of uniform size and material is at its middle point. This proposition is too evident to require demonstration.

The Center of Gravity of the Perimeter of a Triangle is at the center of the circle inscribed in the triangle formed by the lines joining the middle points of the sides of the given triangle. Thus, let ABC (Fig. 12) be the given triangle. To find the center of gravity of its perimeter, find the middle points, D, E and F, and connect them by straight lines. The center of the circle inscribed in the triangle formed by these lines will be the center of gravity sought.

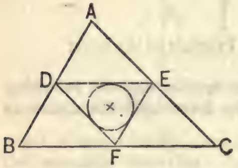

Fig. 12. Center of Gravity of Perimeter of Triangle

Center of Gravity of Symmetrical Lines. The center of gravity of a line which is symmetrical with reference to a point is at that point. Thus the center of gravity of the circumference of a circle or of an ellipse is at the geometrical center of the figures. The center of gravity of the perimeter of an equilateral triangle, or of a regular polygon, is at the center of the inscribed circle. The center of gravity of the perimeter of a square, rectangle, or parallelogram is at the intersection of the diagonals of those figures.

Center of Gravity of a Surface. A SURFACE here means a very thin plate or shell. If a surface can be divided by a line into two symmetrical halves, the center of gravity will be on that line; if it can thus be divided by two lines, the center of gravity will be at their intersection.

Center of Gravity of Regular Figures. The center of gravity of the surface of a circle or an ellipse is at the geometrical center of the figure; of an equilateral triangle or regular polygon, at the center of the inscribed circle; of a parallelogram, at the intersection of the diagonals; of the surface of a sphere, or of an ellipsoid of revolution, at the geometrical center of the body; and of the convex surface of a right cylinder, at the middle point of the axis of the cylinder.

Center of Gravity of Irregular Figures. Any figure bounded by straight lines may be divided into rectangles and triangles, and, the center of gravity of each part being found, the center of gravity of the whole figure may be determined by treating the centers of gravity of the separate parts as particles whose weights are proportional to the areas of the parts they represent.

Center of Gravity of Triangles. To find the center of gravity of a triangle, draw a line from each of two angles to the middle of the opposite side. The intersection of the two lines is the center of gravity.

Center of Gravity of Quadrilaterals. To find the center of gravity of any quadrilateral, draw the diagonals, and from that end of each diagonal which is farthest from the intersection, lay off, toward the intersection, the length of its shorter segment. The two points thus formed, together with the point of

intersection, will form a triangle whose center of gravity is that of the quadrilateral. Thus, let Fig. 13 be a quadrilateral whose center of gravity is to be found. Draw the diagonals AD and BC, and from A lay off $AF = DE$, and from B lay off $BH = CE$. From E draw a line to the middle of FH, and from F a line to the middle of EH. The point of intersection of these two lines is the center of gravity of the quadrilateral. This is a method commonly used for finding the centers of gravity of the voussoirs of an arch.

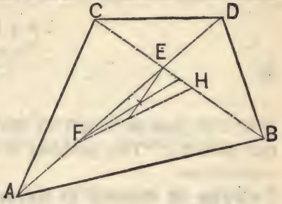

Fig. 13. Center of Gravity of Quadrilateral

Table of Centers of Gravity. Let a be a line drawn from the vertex of a figure to the middle point of the base, and D the distance from the vertex to the center of gravity of the figure. Then (Fig. 14):

In an isosceles triangle	$D = \frac{2}{3} a$
In a segment of a circle, vertex at center of circle	$D = \dfrac{\text{chord}^3}{12 \times \text{area}}$
In a sector of a circle, vertex at center of circle	$D = R \times \dfrac{2 \times \text{chord}}{3 \times \text{arc}}$
In a semicircle, vertex at center of circle	$D = \dfrac{4R}{3\pi} = 0.4244\,R$
In a quadrant of a circle	$D = \frac{3}{5} R$
In a semiellipse, vertex at center of circle	$D = 0.4244\,a$
In a parabola, vertex at intersection of axis with curve	$D = \frac{3}{5} a$
In a cone or pyramid	$D = \frac{3}{4} a$

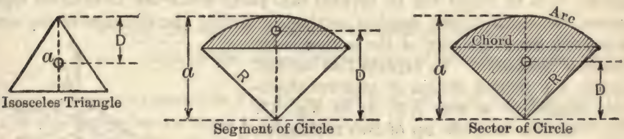

Fig. 14. Center of Gravity of Triangle, Segment and Sector

In a frustum of a cone or pyramid, let h = the height of the complete cone or pyramid, h_1 = the height of the frustum, and let the vertex be at the apex of the complete cone or pyramid; then,

$$D = \frac{3\,(h^4 - h_1^4)}{4\,(h^3 - h_1^3)}$$

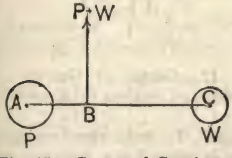

Fig. 15. Center of Gravity of Two Heavy Particles

Center of Gravity of Two Heavy Particles. Let P be the weight of a particle at A (Fig. 15), and W that of a particle at C. The center of gravity is at some point, B, on the line joining A and C. The point B must be so situated that if the two particles were held together by a stiff wire and supported at B by a force equal in magnitude to the sum of P and W they would be in equilibrium. The problem then is

solved by the PRINCIPLE OF THE LEVER, and we have the proportion (see Three Parallel Forces. The Principle of the Lever),

$$P + W : P :: AC : BC$$

or

$$BC = \frac{P \times AC}{P + W}$$

If $W = P$, then $BC = AB$, or the center of gravity will be half-way between the two particles. This problem is of great importance and has many practical applications.

Center of Gravity of Several Heavy Particles. Let W_1, W_2, W_3, W_4 and W_5 (Fig. 16) be the weights of the particles. Join W_1 and W_2 by a straight line and find their center of gravity A, as in the preceding problem. Join A with W_3 and find the center of gravity B, which will be the center of gravity of the three weights W_1, W_2, W_3. Proceed in the same way with each weight. The last center of gravity found will be the center of gravity of all the particles. In both of these cases the lines joining the particles are supposed to be horizontal lines, or else the horizontal projections of the straight lines which join the points.

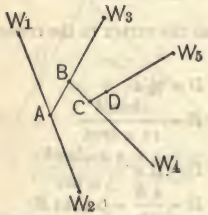

Fig. 16. Center of Gravity of Several Heavy Particles

Center of Gravity of Compound Sections Found by Moments. To determine the strength of a beam having an unsymmetrical cross-section, it is first necessary to determine the distance of the center of gravity of this section from the upper or lower surface of the beam. Various other computations, also, involve finding the center of gravity of an irregular figure, so that the problem is one of practical importance. If the figure of which the center of gravity is to be found can be divided into parts which are themselves regular figures, the readiest and simplest method of finding the distance of the center of gravity from one edge of the section is by means of MOMENTS. To explain this method assume a T-shaped section of uniform thickness, hinged on a wire XX, as in Fig. 17. The T section is made up of two rectangles, one forming the flange, the other the web. The center of gravity of each rectangle is at its own center of figure and may be readily found. If the T section is placed horizontally, as in the figure, the axis XX being fixed, it will immediately, by the force of gravity, revolve about the axis until it becomes vertical, and the sum of the moments of the forces causing the revolution is $A' \times d' + A'' \times d''$, A' representing the weight of the web and A'' the weight of the flange. To hold the T section in a horizontal position, there must be a moment of some force acting in an opposite, or upward, vertical direction and just equal to the sum of the two moments causing revolution downwards. If the force A, of this moment, tending to cause revolution upward, is equal to the weight of the entire T section, it must be applied at the center of gravity of the entire figure to make its moment just equal to the sum of the moments of the two downward forces.

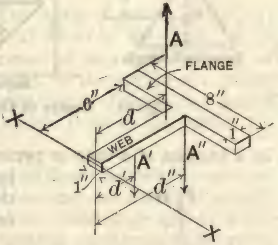

Fig. 17. Center of Gravity of Compound Sections by Moments

But the moment of A is $A \times d$, therefore d is the distance from the end of the web, or from the axis XX, to the center of gravity of the entire figure. Therefore, since $A \times d = A' \times d' + A'' \times d''$,

$$d = \frac{A' \times d' + A'' \times d''}{A} \tag{1}$$

As the weight of any homogeneous material of uniform thickness is proportional to the area, A, A' and A'' may be used to represent areas as well as weights. Expressing formula (1) as a rule, we have:

Center of Gravity of Compound Figures. The distance of the center of gravity of a compound figure from any line of reference is equal to the sum of the products, obtained by multiplying the area of each of the simple parts into which the compound figure is divided by the distances of its center of gravity from the line of reference, divided by the area of the entire figure. This rule applies to any compound figure.

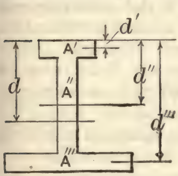

Fig. 18. Center of Gravity of Tees, Angles, Channels, etc.

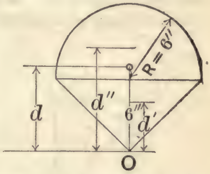

Fig. 19. Center of Gravity of Irregular I Section

Example I. Assume that the T section shown in Fig. 17 has the dimensions indicated. Then A' equals 6, A'' equals 8, and A equals 14 sq in; and d' equals 3 and d'' equals $6\frac{1}{2}$ in. The sum of the products of A' by d' and A'' by d'' is $18 + 52$ or 70 sq in $\times$ in, and this divided by 14 sq in, the area of the entire figure, gives 5 in for the distance d. The distance d of the center of gravity from the top of the webs, in each of the figures shown in Fig. 20, is found by the following formula:

$$d = \frac{\text{area of the web or webs} \times d'/2 + \text{area of flange} \times d''}{\text{area of the web or webs} + \text{area of flange}} \tag{2}$$

For a section like that shown in Fig. 18, in which A', A'' and A''' represent the areas of the respective rectangles, the distance d of the center of gravity from the top may be found by the formula

$$d = \frac{A' \times d' + A'' \times d'' + A''' \times d'''}{A' + A'' + A'''} \tag{3}$$

Example II. To show the application of the rule for finding the center of gravity of compound figures, take the one shown in Fig. 19. The distance d

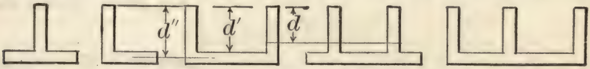

Fig. 20. Center of Gravity of Irregular Figures

of the center of gravity of the entire figure from the vertex O is found as follows: The area of the triangle is 36 sq in and of the semicircle 56.5 sq in. From the Table of Centers of Gravity (page 293) the distance of the center of gravity of an isosceles triangle from the vertex is two-thirds its height, which gives 4 in as

the value for d'. The center of gravity for a semicircle is 0.4244 R from its base, so that d'' equals 8.54 in. Then,

$$d = \frac{36 \times 4 + 56.5 \times 8.54}{36 + 56.5} = 6.77 \text{ in}$$

This method of finding the center of gravity is similar to that explained in Chapter IX for finding the supporting forces or reactions. In the latter case, however, the problem is to find the balancing forces instead of the lever-arms.

CHAPTER VII

STABILITY OF PIERS AND BUTTRESSES

BY
GRENVILLE TEMPLE SNELLING
MEMBER OF AMERICAN INSTITUTE OF ARCHITECTS

Mechanical Principles. A pier or buttress may be considered STABLE when the forces acting upon it do not cause it to ROTATE or TIP OVER nor cause any course of masonry to SLIDE on its bed; some parts, however, of the masonry may be CRUSHED. When a pier sustains a vertical load only, it might be considered STABLE, but it might not have sufficient STRENGTH. It is only when the pier receives a THRUST, as from a rafter or an arch, that its stability must be considered. In order that there may be no rotation, the MOMENT OF THE THRUST (Chapter VI) against the pier about any point in its outside edge must not exceed the MOMENT OF THE WEIGHT of the pier about the same point.

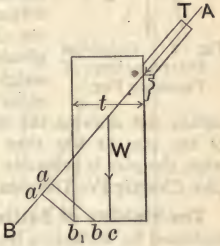

Fig. 1. Pier with Thrust

To illustrate let us consider the pier shown in Fig. 1. Let us suppose that this pier receives the foot of a rafter which exerts a THRUST T in the direction AB. The tendency of this thrust is to cause the pier to rotate about the outer edge b_1, and the MOMENT OF THE THRUST about this point, which is the measure of this tendency to rotate, is $T \times a'b_1$, $a'b_1$ being the lever-arm of the moment. For UNSTABLE EQUILIBRIUM, only, the MOMENT OF THE WEIGHT of the pier about the same edge must just equal $T \times a'b_1$. The resultant force representing the weight of the pier acts vertically through its center of gravity which in this case is equidistant from its sides; and its lever-arm is b_1c, or one-half its thickness.

Hence, for equilibrium of moments, we must have the equation

$$T \times a'b_1 = W \times b_1c$$

But in this condition the least additional thrust, or the crushing of the outer edge, will cause the pier to rotate; hence, for safety, we must use some FACTOR OF SAFETY. This is sometimes done by making the moment of the weight equal to that of the thrust when referred to a point in the bottom of the pier, a certain distance in from the outer edge. This distance for piers or buttresses should not be less than one-fourth the thickness of the pier.

Representing this point in the figure by b, we have the necessary equation for the safe stability of the pier

$$T \times ab = W \times t/4$$

t being the width of the pier.

We cannot from this equation determine the dimensions of a pier to resist a given thrust, because we have the distance ab, t and W, all unknown quantities. Hence we must first assume a tentative size for the pier, find the length of the line ab, and see if the MOMENT OF THE WEIGHT of the pier is equal to the MOMENT OF THE THRUST. If it is not we must assume another size for the pier. In point of fact the steps of the problem usually present themselves in the

inverse order, the pier or buttress being given and the determination of its stability being required. The size of the pier or buttress is usually first determined rather from the architectural exigencies of the design than from the engineering requirements for the stability of the structure. If upon investigation these are not in accord, it is the duty of the designers to use their ingenuity in seeing that both conditions are fufillled.

The Stability of Piers and Buttresses. When it is desired to determine if a given pier or buttress is capable of resisting a given thrust, the problem can be solved GRAPHICALLY in the following manner. Let *ABCD* (Fig. 2) represent a pier which sustains a given thrust *T* at *B*. To determine whether the pier will safely sustain this thrust, we proceed as follows:

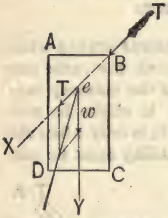

Fig. 2. Graphical Determination of Thrust on Pier

Draw the indefinite line *BX* in the direction of the thrust. Through the center of gravity of the pier, which in this case is midway between *AD* and *BC*, draw a vertical line intersecting the line of the thrust at *e*. As a force may be considered to act anywhere along its line of action, we may consider that the thrust and the weight act at the point *e*. The resultant of these two forces is obtained by laying off the thrust *T* from *e* on *eX*, and the weight of the pier *W*, from *e* on *eY*, both to the same scale of so many pounds to the inch, completing the parallelogram and drawing the diagonal. If this diagonal, prolonged, cuts the base of the pier at less than one-third the width of the base from the outer edge, the pier is generally considered unstable and its dimensions are changed. (See Chapter IV, Theorem of the Middle Third.)

The Stability of Buttress with Offsets. THE STABILITY OF A PIER may be increased by adding to its weight by placing some heavy material on top, for example, or by increasing its width at the base by means of OFFSETS, as in Fig. 3. Figs. 3 and 4 show the method of determining the stability of a buttress with offsets. The first step is to find the vertical line passing through the center of gravity of the whole pier. This is best done by dividing the buttress into quadrilaterals, as *ABCD*, *DEFG* and *GHIK* (Fig. 3), finding the center of gravity of each quadrilateral by either the method of diagonals or triangles as explained in Chapter VI, and then measuring the perpendicular distances X_1, X_2, X_3 from the different centers of gravity to the line *KI*. (See, also, Chapter VIII, page 313).

Multiply the area of each quadrilateral by the distance of its center of gravity from the line *KI* and add together the areas and the products. Divide the sum of the products by the sum of the areas and the result will be the distance of the center of gravity of the whole buttress from *KI*. This distance we denote by X_0. This calculation is a practical application of the theorem in mechanics that the MOMENT OF THE RESULTANT of any number of forces about a given point is equal to the SUM OF MOMENTS of the individual forces about that point.

Example 1. Let the buttress shown in Fig. 3 have the dimensions shown. Then the areas of the quadrilaterals and the distances from their centers of gravity to *KI* are as follows:

First area =	35 sq ft	$X_1 = 0'.95$	First area $\times X_1 = 33.25$
Second area =	23 sq ft	$X_2 = 2'.95$	Second area $\times X_2 = 67.85$
Third area =	11 sq ft	$X_3 = 4'.95$	Third area $\times X_3 = 54.45$
Total area,	69 sq ft		Total moments, 155.55

The sum of the moments of the areas is 155.55, and dividing this by the total area, we have 2.25 as the distance X_0. Measuring this to the scale of the drawing from *KI*, we have a point through which the vertical line passing through the center of gravity must pass.

This line, passing through the center of gravity of the buttress, can be found GRAPHICALLY, also, by the method of the EQUILIBRIUM POLYGON (Fig. 3). (See,

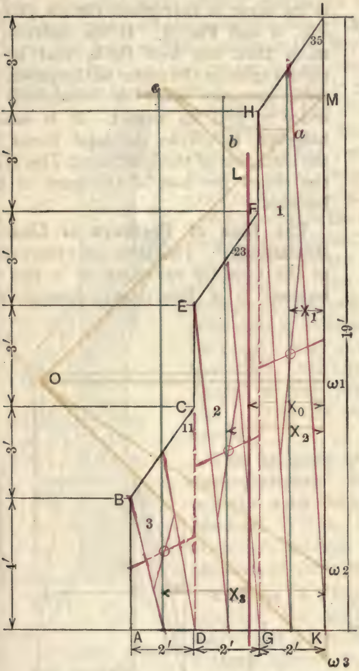

Fig. 3. Buttress with Offsets

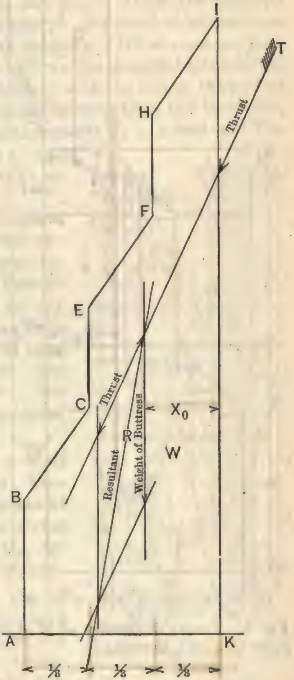

Fig. 4. Resultant Thrust on Buttress with Offsets

also, Chapter VIII, Fig. 12, etc.) In order to do this, lay off at any convenient scale, beginning at some convenient point *M*, *Mw* 1, *w* 1 *w* 2, and *w* 2 *w* 3, the areas of the various quadrilaterals composing the buttress. Through the center of gravity of each quadrilateral draw a vertical (green) line. Draw the lines *MO* and *w* 3 *O*, intersecting at some conveniently chosen POLE-POINT, *O*. Draw *Ow* 1 and *Ow* 2. Through *a*, where *MO* intersects the vertical (green) line drawn through the center of gravity of the first quadrilateral, draw *ab* parallel to *Ow* 1, and through *b*, where *ab* intersects the (green) line through the center of gravity of the second quadrilateral, draw *bc* parallel to *Ow* 2. Finally draw *cL* parallel to *Ow* 3. Where this line intersects *MO* at *L* will be the point through which the (heavy red) line, passing through the center of gravity of the buttress taken as a whole, should be drawn. The distance

X_0, measured from IK, should then be 2.25 ft or very nearly this, allowing for slight errors of drawing, and the same as that found by MOMENTS. Fig. 5 shows the same method of determining the position of the center of gravity of a buttress similar to the one illustrated in Fig. 9.

After this line is found, the method of determining the stability of the pier is the same as that given for the pier in Fig. 2 and Fig. 4. If the buttress is more than one foot thick, that is, at right-angles to the plane of the paper, its cubic contents must be determined in order to find its weight. It is easier, however, to divide the total thrust by the thickness of the buttress. This gives the thrust per foot of thickness of the buttress.

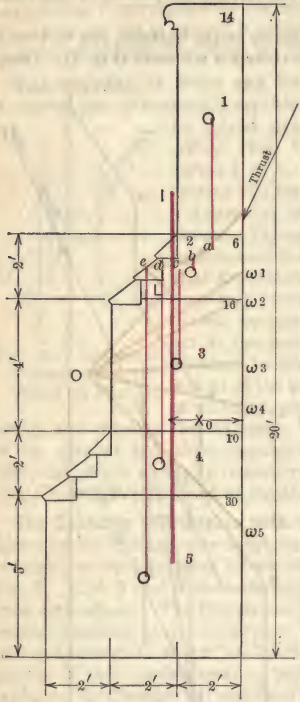

Fig. 5. Center of Gravity of Wall and Buttress

The Line of Pressure or Line of Resistance.* The LINE OF RESISTANCE or the LINE OF PRESSURE of a pier or buttress is a line drawn through the CENTER OF PRESSURE of each joint. The CENTER OF PRESSURE of any joint is the point in which the resultant of the forces acting on that portion of the pier above the joint cuts it. The line of pressure, or of resistance, when drawn in a pier, shows how near the greatest stress on any joint comes to the edges of that joint. It can be drawn by the following method.

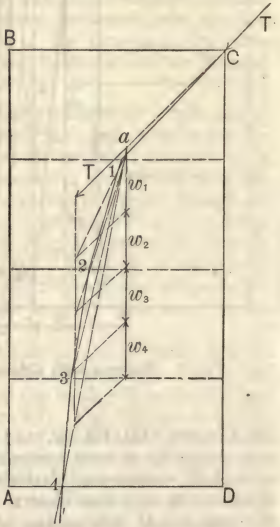

Fig. 6. Line of Pressure in Pier

Let $ABCD$ (Fig. 6) be a pier whose LINE OF PRESSURE we wish to draw. Let T be the thrust against the pier. First, divide the height of the pier into several parts, each 2 or 3 feet high, as shown by the horizontal dotted lines. It is more convenient to make the courses or

* This line is called, interchangeably, the line of pressure, the line of resistance, the resistance-line, etc.

parts equal in height. Prolong the LINE OF THE THRUST, and draw a vertical line through the center of gravity of the pier, intersecting the line of thrust at the point *a*. From *a* lay off to a scale the thrust *T*, and the weights of the different parts of the pier, commencing with the weight of the upper portion. Thus, w_1 represents the weight of the portion above the first joint; w_2 represents the weight of the second part; and so on. The sum of the *w*'s will represent the weight of the whole pier.

Draw a parallelogram, with *T* and w_1 for its two sides. Draw the diagonal and produce it beyond the parallelogram, if necessary. Its point of intersection with the first joint will be a point in the line of pressure. Draw a second parallelogram, with *T* and $w_1 + w_2$ for its two sides. Draw the diagonal intersecting the second joint at the point 2. Continue in this way with the rest of the partial weights, the last diagonal intersecting the base *AD*, in the point 4. Join the points 1, 2, 3 and 4. The resulting broken line *C*1234 is the LINE OF PRESSURE or LINE OF RESISTANCE.

We have taken the simplest case as an example; but the same principles are true for any case. If the line of pressure of the pier at any point falls at a distance from the outside edge of the joint less than ONE-THIRD THE WIDTH OF THE JOINT, the pier is generally considered unsafe.

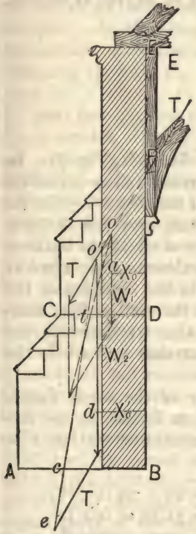

Fig. 7. Stability of Wall and Buttress

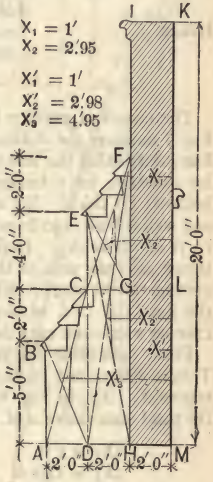

Fig. 8. Stability of Wall and Buttress

The Stability of a Wall and Buttress. By Moments and Graphical Method. The following example illustrates the application of these principles.

Example 2. Let Fig. 7 represent the section of a side wall of a church, with a buttress against it. Opposite the buttress, on the inside of the wall, is a hammer-beam truss, which we will suppose exerts an outward thrust on the wall of the church, amounting to about 9 600 lb. We will further consider that the resultant of the thrust acts at *P*, and at an angle of 60° with the horizontal. The dimensions of the wall and buttress are given in Fig. 8. The buttress is 2 ft thick, at right-angles with the plane of the paper. Has the buttress the proper SIZE and FORM to enable the wall to resist the thrust of the truss?

The first point to decide is whether or not the LINE OF PRESSURE cuts the joint *CD* at a safe distance in from *C*. To ascertain this we must determine the position of the center of gravity of the wall and buttress above the joint *CD* (Fig. 7). One way to determine this is by the METHOD OF MOMENTS, the MOMENTS OF THE AREAS being taken about the line *KM* as an axis, or line of reference (Fig. 8), as already explained. The distance X_1 is, of course, half the thickness of the wall or 1 ft. We next find the center of gravity of the part

CEFG (Fig. 8) by the method of diagonals; and scaling the distance X_2, we find it to be 2.95 ft.

The area $CEFG = A_2 = 10$ sq ft; and the area $GIKL = A_1 = 26$ sq ft. Let A = the total area above *CL*.

Then we have

$$\begin{array}{lll} X_1 = 1 \text{ ft} & A_1 = 26 \text{ sq ft} & A_1 \times X_1 = 26 \text{ sq ft} \times \text{ft} \\ X_2 = 2.95 \text{ ft} & A_2 = 10 \text{ sq ft} & A_2 \times X_2 = 29.5 \text{ sq ft} \times \text{ft} \\ \hline & A = 36 \text{ sq ft} & 36)55.5 \text{ sq ft} \times \text{ft} \\ \hline & & X_0 = 1.5 \text{ ft} \end{array}$$

Expressed in EQUATIONS OF MOMENTS OF AREAS, this may be written as follows, A representing the total area above the line *CL* (Fig. 8):

$$A \times X_0 = (A_1 \times X_1) + (A_2 \times X_2)$$

Hence,

$$X_0 = \frac{(A_1 \times X_1) + (A_2 \times X_2)}{A}$$

The center of gravity is at a distance 1.5 ft from the line *ED* (Fig. 7). In Fig. 7 measure the distance $X_0 = 1.5$ ft, and through the point *a* draw a vertical line intersecting the line of the thrust prolonged at *O*. If the thrust is 9 600 lb, for example, for a buttress 2 ft thick, it will be half that, or 4 800 lb, for a buttress 1 ft thick. We will call the weight of the masonry of which the buttress and wall is built, 150 lb per cu ft. Then the thrust is equivalent to 4800/150 = 32 cu ft of masonry. Laying this off to a scale from *O*, in the direction of the thrust, and the area of the masonry, 36 sq ft, from *O* on the vertical line, completing the rectangle, and drawing the diagonal, we find that the diagonal cuts the joint *CD* at *t*, within the limits of safety. We must next find where the LINE OF PRESSURE cuts the base *AB*.

First, determine the position of the center of gravity of the whole figure. This is determined by finding, as explained for the distances X_1 and X_2, the distances X_2', X_3', in Fig. 8, and making the following computation, letting A' = the total area above *AM*.

$$\begin{array}{lll} X_1' = 1 \text{ ft} & A_1' = 40 \text{ sq ft} & A_1 \times X_1 = 40 \text{ sq ft} \times \text{ft} \\ X_2' = 2.98 \text{ ft} & A_2' = 24 \text{ sq ft} & A_2 \times X_2 = 71.52 \text{ sq ft} \times \text{ft} \\ X_3' = 4.95 \text{ ft} & A_3' = 12 \text{ sq ft} & A_3 \times X_3 = 59.40 \text{ sq ft} \times \text{ft} \\ \hline & A' = 76 \text{ sq ft} & 76)170.92 \text{ sq ft} \times \text{ft} \\ \hline & & X_0' = 2.25 \text{ ft} \end{array}$$

This, also, may be expressed in EQUATIONS OF MOMENTS OF AREAS, as explained for the part above the line *CL*.

Then from the line *EB* (Fig. 7) lay off the distance $X_0' = 2.25$ ft, and draw through *d* a vertical line intersecting the line of the thrust at O'. On this vertical line, measure down from O' the whole area 76, to scale, as explained above, and from the lower extremity of this line representing the area, lay off, at the proper angle, the thrust $T = 32$. Draw the line $O'e$, intersecting the base at *c*. This is the point where the LINE OF PRESSURE cuts the base; and, as it is at a safe distance in from *A*, the buttress has sufficient stability. If there were more offsets, we should proceed in the same way, finding where the LINE OF PRESSURE cuts the joint at the top of each offset. The reason for doing this is

because the LINE OF PRESSURE might cut the base at a safe distance from the outer edge, while higher up it might come outside of the buttress or too near the outside face, thus making the buttress unstable. The method given in these examples is applicable to piers of any shape or material. If the LINE OF PRESSURE makes an angle of less than 30° with any horizontal joint, the stones above the joint may SLIDE at this joint, or at least have a strong tendency to do so. SLIDING can be prevented either by doweling, or by inclining the joints. Such conditions, however, are rare in architectural construction.

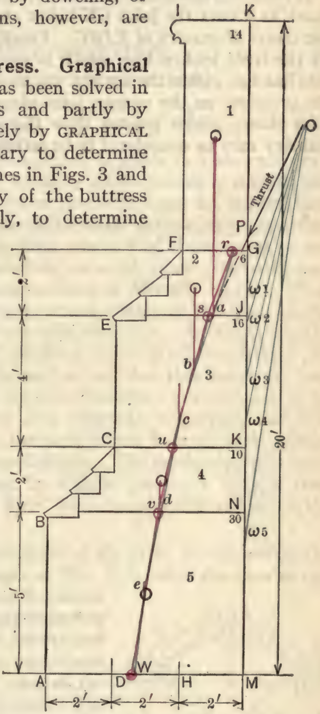

Fig. 9. Line of Pressure in Wall and Buttress

The Stability of a Wall and Buttress. Graphical Method. This same example, which has been solved in the foregoing case partly by MOMENTS and partly by GRAPHICAL METHODS, can be solved entirely by GRAPHICAL METHODS. In this case it is not necessary to determine the position of the line (the heavy red lines in Figs. 3 and 5) passing through the center of gravity of the buttress taken as a whole. It is necessary, only, to determine the (red) lines passing through the centers of gravity of the various trapezoids and rectangles into which it has been subdivided. To determine the position of the LINE OF PRESSURE and the various CENTERS OF PRESSURE on the different joints, the method shown in Fig. 6 may be used. The construction shown in that figure, in which the complete parallelograms of the forces acting at each joint are drawn, may be simplified. One-half the parallelogram, only, or the TRIANGLE OF THE FORCES acting at each joint, may be drawn and the whole construction placed at one side of the figure and afterwards transferred to the figure itself by means of parallel lines.

Draw the joint-planes *FG*, *EJ*, *CK* and *BN* and calculate the areas of the various parts of the wall and buttress, such as *IKGF*, *FGJE*, *EJKC*, *CKNB* and *BNMA*, Fig. 9. These are respectively 14 sq ft, 6 sq ft, 16 sq ft, 10 sq ft and 30 sq ft. Lay off these areas to a scale of so many square units to a linear unit, at *Pw* 1, *w* 1 *w* 2, *w* 2 *w* 3, *w* 3 *w* 4 and *w* 4 *w* 5, along the line *KM*, beginning at the point of application of the THRUST. Lay off, at the same scale, the thrust *OP* for one foot of thickness of the wall, and let this thrust be 4 800 lb. Draw *Ow* 1, *Ow* 2, *Ow* 3, etc. Then *Ow* 1 will be the resultant of the thrust and the weight of the buttress above the joint *FG*, *Ow* 2 will be the resultant of this last resultant and the weight of that part of the buttress between the joints *FG* and *EJ*, and so on until *Ow* 5 is reached, which is the resultant of the total weight of the buttress and the thrust as well as the resultant of the rectangle *BNMA* and the previous resultant. Prolong the thrust *OP*, until it cuts the first (red) line through the center of gravity of the first rectangle *IKGF*, at *a*. Through this point draw a (green) line parallel to *Ow* 1 and prolong it backward

until it intersects the joint *FG* at the point within the small (red) circle. This determines the CENTER OF PRESSURE on this joint. Next, draw *ab* (green) parallel to *Ow* 2 and prolong it backward until it intersects the joint *EJ*, at the CENTER OF PRESSURE on that joint. Repeat this operation to obtain the CENTERS OF PRESSURE on each successive joint, drawing *bc*, *cd* and *de* parallel respectively to *Ow* 3, *Ow* 4 and *Ow* 5.

It must be remembered, however, that *cd* does not have to be prolonged backward, as it cuts the joint *CK* below and to the left of the line passing through the center of gravity of *EJKC*. Finally, join the various CENTERS OF PRESSURE by the (red) broken line, which is the LINE OF PRESSURE in the buttress. As this line lies within the MIDDLE THIRD of the construction, and the resultants of the pressures on the various joint-planes do not make with the normals to the joint-planes angles greater than the ANGLE OF FRICTION, the conditions for stability may be considered to be satisfied.

CHAPTER VIII

THE STABILITY OF MASONRY ARCHES

By

GRENVILLE TEMPLE SNELLING

MEMBER OF AMERICAN INSTITUTE OF ARCHITECTS

1. Arches

The Lintel and the Arch. When an opening is made in a masonry wall it is necessary to provide some means of spanning such opening to support the superimposed masonry. Two methods have been employed by constructors for this purpose. The first involves the use of the BEAM, GIRDER, CAP, or LINTEL, and the second the throwing of an ARCH from one side of the opening to the other. LINTELS are made of various materials, as wood, stone, reinforced concrete, cast iron and steel, and have cross-sections of different shapes. They are placed across the tops of the openings and transfer laterally the loads above, causing VERTICAL REACTIONS, only, in the side supports. An ARCH, on the contrary, is a particular arrangement of blocks of stone or other material, put together, generally along a curved line, in such a way that they resist the load by a balancing of certain THRUSTS and COUNTERTHRUSTS. An arch exerts on its supports an OUTWARD THRUST as well as a VERTICAL PRESSURE; and it is this outward thrust which requires that the arch should be used with caution when the abutments are not amply large and strong. The mechanical principles involved in the spanning of an opening by a lintel are much simpler than those of the arch and, historically, the lintel very considerably antedates the arch.

Definitions. Before taking up the principles of the arch, we will define the principal terms relating to it. The distance *ec* (Fig. 1) is called the SPAN of the arch; *ai*, the rise; *b*, the CROWN; the lower boundary line *eac*, the SOFFIT or INTRADOS; the outer boundary line, the BACK or EXTRADOS. The terms SOFFIT and BACK are also applied to the entire lower and upper curved sufaces of the whole arch. The sides of the arch which are seen are called the FACES. The blocks of which the arch itself is composed are called VOUSSOIRS; the center one, *K*, is called the KEYSTONE; and the lowest ones, *SS*, the SPRINGERS. In SEGMENTAL arches, or those of which the intrados is not a complete semicircle, the springers generally rest upon two stones, as *RR*, which have their upper surfaces cut to receive them; these stones are called SKEWBACKS. The line connecting the lower edges of the springers is called the SPRINGING-LINE; the sides of the arch are called the HAUNCHES; and the loads in the triangular spaces, between the haunches and a horizontal line drawn from the crown, are called the SPANDRELS. The blocks of masonry, or other material, which support two successive arches, are called PIERS; and the extreme blocks, which, in the case of stone bridges, generally support, on one side, embankments of earth, are called ABUTMENTS. A pier strong enough to resist the thrust of one of two successive arches, in case the other one falls down, is some-

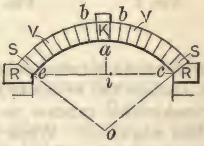

Fig. 1. Diagram of Segmental Arch

times called an ABUTMENT-PIER. Besides their own weight, arches usually support permanent loads or SURCHARGES of masonry or of earth.

Forms of Arches. In using arches in architectural constructions, the FORMS of the arches are generally governed by the style of the building, or by a limited amount of space, rather than by engineering considerations. The problem, therefore, that usually presents itself to the architect is not to design the form and dimensions of an arch that will most economically and, from an engineering point of view, efficiently bear its load, but rather to determine if an arch of a certain form and of certain dimensions will be stable and safe under its load. The SEMICIRCULAR and SEGMENTAL forms of arches are the best as regards stability, and are the simplest to construct. ELLIPTICAL and THREE-CENTERED arches are not as strong as circular arches, and should only be used where they can be given all the strength desirable.

The Strength of an Arch depends very much upon the care with which it is built and upon the quality of the materials. In stone arches, special care should be taken to cut and lay the beds of stones accurately, and to make the bed-joints thin and close, in order that the arches may be stressed as little as possible in settling. To insure this, arches are sometimes built DRY, grout or liquid mortar being afterwards run into the joints; but the advantage of this method is doubtful.

Brick Arches.* (See Figs. 2, 3, 4 and 5.) These may be built either of WEDGE-SHAPED bricks, molded or rubbed so as to fit to the radius of the soffit,

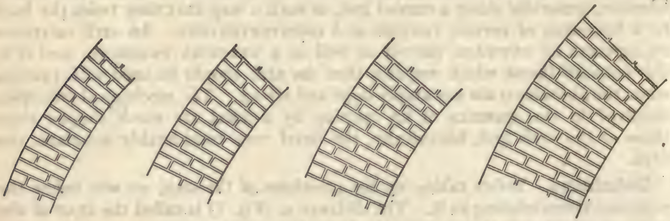

Fig. 2 Fig. 3 Fig. 4 Fig. 5
Brick Arches

or of bricks of COMMON SHAPE. The former method is undoubtedly the best, as it enables the bricks to be thoroughly bonded, as in a wall; but, as it involves considerable expense to make the bricks of the proper shape, it is very seldom employed. When bricks of the ordinary shape are used, they are accommodated to the curved figure of the arch by making the bed-joints thinner towards the intrados than they are at the extrados; or, if the curvature is sharp, by driving thin pieces of slate into the outer edges of those joints; and different methods are followed for BONDING them.

The usual method is to build the arch in concentric rings, each one-half brick thick; that is, to lay all the bricks as STRETCHERS and depend upon the tenacity of the mortar for the connection of the several rings. Brick masonry constructed in this way is deficient in strength, unless the bricks are laid in cement mortar which is at least as tenacious as themselves. Another way is to introduce courses of HEADERS at intervals, and to connect pairs of half-brick rings

* For illustrations of the different methods of building brick arches, see Chapter VII, Building Construction and Superintendence, Part I, Masons' Work, F. E. Kidder.

together. This may be done either by thickening with pieces of slate the joints of the outer ring of a pair of half-brick rings, so that there will be the same number of courses of stretchers in each ring between two courses of headers; or by placing the courses of headers at such distances apart, that between each pair of them there will be one course of stretchers more in the outer than in the inner ring. The former method is best suited to arches of long radius; the latter, to those of short radius. HOOP-IRON laid around the arch, between half-brick rings, as well as longitudinally and radially, is very useful for strengthening brick arches. The bands of hoop-iron which traverse the arch radially may also be bent, and prolonged into the bed-joints of the backing and spandrels. By the aid of HOOP-IRON BOND, Sir Marc-Isambard Brunel built a half-arch of bricks, laid in strong cement mortar, which stood, projecting from its abutment like a bracket to the distance of 60 ft, until it was destroyed by the undermining of its foundations.

The only requirements in the New York City Building Laws for brick and stone arches is that "openings for doors and windows in all buildings shall have good and sufficient arches of stone, brick, or terra-cotta, well built and keyed and with good and sufficient abutments."

Rule for the Radius of Brick Arches. A good RULE for the radius of segmental brick arches over windows, doors and other small openings is to make the RADIUS EQUAL TO THE WIDTH OF THE OPENING. This gives a good rise to the arch and a pleasing proportion. In common brickwork, when no particular architectural effect is desired, such as in the rowlock arches thrown over the openings in cellar walls, a RULE in very common use is to make the RISE of the arch at the crown AN INCH IN HEIGHT FOR EVERY FOOT OF SPAN.

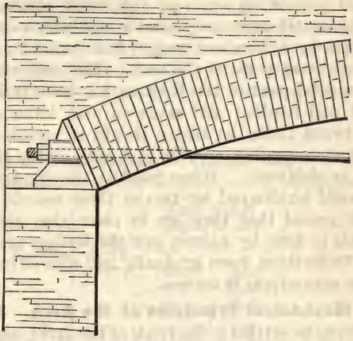

Fig. 6. Segmental Brick Arch, Cast-iron Skewback and Wrought-iron Tie-rod

Segmental Arches with Tie-Rods. It is often desirable to span openings in a wall by means of arches when there are not a sufficient number of abutments to withstand the thrusts. In cases of this kind each arch can be sprung from two cast-iron SKEWBACKS, held in place by IRON RODS, as is shown in Fig. 6. When this is done, it is necessary to proportion the size of the rods to the THRUST of the arch. The HORIZONTAL THRUST of the arch may be very closely determined by the following formula:

$$\text{Horizontal thrust} = \frac{\text{load on arch} \times \text{span}}{8 \times \text{rise of arch in feet}}$$

If the load is concentrated at the center of the arch, the thrust will be twice that given by this formula.

The TENSIONAL STRESS in the rod or rods will equal the HORIZONTAL THRUST of the arch and if there are two rods, the stress in each will be one-half the thrust. If there are three rods, then each must resist one-third the thrust. Knowing the stresses in the rods, the size of each may be determined from Table II, Chapter XI.

Example 1. Let us assume that a brick arch, like the one shown in Fig. 6, has a span of 15 ft, a rise at the center of 1 ft 6 in, and that it supports a 12-in brick wall. The weight of all the brick masonry above the arch does not come upon it. Usually only an EQUILATERAL TRIANGLE of brickwork is considered, the base of the triangle being the span. Assume, therefore, an equilateral triangle the sides of which are each 15 ft long. The altitude of this triangle is about 12.6 ft and its area will equal 15 ft × 12.6 ft × ½ = 94½ sq ft. If the wall is 12 in thick there will be 97½ cu ft of brickwork within this triangle of the wall; and since ordinary brickwork weighs about 115 lb per cu ft, its weight will be about 10 867 lb. Substituting these values in the formula,

$$\text{The horizontal thrust} = \frac{10\,867 \times 15}{8 \times 1.5} = 13\,584 \text{ lb}$$

Looking in Table II, page 388, it appears that one 1½-in or two 1⅛-in plain, round, wrought-iron rods, or one 1⅛-in or two ¾-in round, upset, steel rods should be used.

Centers for Arches. A CENTER is a temporary structure, generally of timber, on which the voussoirs of an arch are supported while the arch is being built. It consists of parallel frames or ribs, placed at convenient distances apart, curved on the outside to a line parallel to that of the soffit of the arch, and supporting series of transverse planks, upon which the arch-stones rest. The center commonly used is one which can be lowered, or STRUCK all in one piece, by driving out wedges from below it, so as to remove at once the support from every point of the arch. The center of an arch should not be struck until the solid part of the backing has been built and the mortar has had time to set and harden; and when an arch forms one of a series of arches with piers between them, no center should be struck so as to leave a pier with an arch abutting against one side of it only, unless the pier has sufficient stability to act as an abutment. When possible, the STRIKING of the center of large brick arches should be delayed for two or three months after the arch is built, and during the period that they are in place they should be EASED from time to time. This is done by EASING OUT the wedges under the centers a little at a time so as to let them down gradually and thus adjust any slight settling or shrinkage of the masonry as it occurs.

Mechanical Principles of the Arch. In designing an arch, the first question to be settled is the FORM of the arch; and in regard to this, as already noted, there is generally little choice. When the abutments are of ample size, the SEGMENTAL ARCH is the strongest; but when it is necessary to make the abutments of the arch as small as possible, the SEMICIRCULAR or the POINTED ARCH should be used.

Depth of Keystone. Having decided upon the form of the arch, the DEPTH OF THE ARCH-RING must next be decided. This is generally determined by computing the required DEPTH OF THE KEYSTONE and making the depth of the whole ring the same or a little larger. In considering the strength of an arch, the depth of the keystone is considered to be only the distance from the extrados to the intrados of the arch; and if the keystone projects above the arch-ring, as in Fig. 1, the projection is considered a part of the load on the arch. There are several rules for determining the depth of the keystone, but all are empirical; and they differ so greatly that it is difficult to recommend any particular one.

Rankine's Formula for Depth of Keystone. Professor Rankine's rule is often quoted, and gives results which are probably true enough for most

arches. It applies to both CIRCULAR and ELLIPTICAL ARCHES and is as follows. Take a mean proportional between the inside radius at the crown, and 0.12 of a foot for a single arch, and 0.17 of a foot for an arch forming one of a series: Or,

$$\text{Depth in feet of keystone for single arch} = \sqrt{(0.12 \times \text{radius at crown})}$$

$$\text{Depth in feet of keystone for arch of a series} = \sqrt{(0.17 \times \text{radius at crown})}$$

The dimensions given by this formula seem to agree very well with those generally used in practice in arches of a certain kind. The formula, however, gives the same depth of keystone for spans of any length, provided the radius is the same; and in this particular it would seem that the rule is not satisfactory.

Trautwine's Formula for Depth of Keystone. Trautwine, from calculations made for a large number of arches, deduced a formula for the depth of keystone, which seems to agree with theory more closely than Rankine's formula. His rule is, for CUT STONE,

$$\text{Depth of key in feet} = \left(\frac{\sqrt{\text{radius} + \text{half span}}}{4}\right) + 0.2 \text{ ft}$$

For SECOND-CLASS work this depth may be increased about one-eighth part, or for BRICKWORK OR FAIR RUBBLE, about one-third.

Tables for Depths of Keystones. Table I gives a few examples of the DEPTHS OF THE KEYSTONES of some bridges, together with the depths which would be required by Trautwine's or Rankine's formula. From this table it is seen that the results of both formulas agree very well with dimensions used in actual practice.

Table I. Depths of Keystones of Some Arches of Circular Arc

Name or location of structure	Span	Rise	Radius	Actual depth of key	Calculated depth of key		Engineer
					Trautwine's Rule	Rankine's Rule	
	ft	ft	ft	ft	ft	ft	
Cabin John, Washington aqueduct	220.0	57.25	134.25	4.16	4.11	4.00	Meigs
Grosvenor bridge Chester, England	200.0	42.00	140.00	4.00	4.07	4.10	Hartley
Dora Riparia, Turin, Italy	148.0	18.00	160.10	4.92	4.03	4.38	Mosca
Tongueland, England	118.0	38.00	64.80	3.50	3.00	2.79	Telford
Dean bridge, Scotland, in a series	90.0	30.00	48.90	3.00	2.62	2.88	Telford
Falls bridge, Philadelphia & Reading Railroad	78.0	25.00	43.00	3.00	2.46	2.27	Steele
Chestnut St. bridge, Philadelphia, brick in cement	60.0	18.00	34.00	2.50	2.20	2.00*	Kneass
Philadelphia & Reading Railroad	44.0	8.00	34.30	2.50	2.08	2.02	Steele
Philadelphia & Reading Railroad	31.2	5.00	26.80	1.66	1.83	1.79	Steele

* For first-class cut-stone work.

Table II* gives the DEPTHS OF KEYSTONES for arches of first-class cut stone, according to Trautwine's Formula. For second-class cut stone, add about one-eighth part and for fair rubble or for brickwork about one-third part, as stated with formula.

Table II. Depths of Keystones for Arches of First-Class Cut-Stone Masonry

Span	Rise, in parts of the span						
	½	⅓	¼	⅕	⅙	⅛	⅒
ft	ft	ft	ft	ft	ft	ft	ft
2	0.55	0.56	0.58	0.60	0.61	0.64	0.68
4	0.70	0.72	0.74	0.76	0.79	0.83	0.88
6	0.81	0.83	0.86	0.89	0.92	0.97	1.03

280	4.38	4.46	4.63	....	....	....	....
300	4.53	4.62	4.80	....	....	....	....

Example 2. Having decided what the thickness of the arch-ring will be it remains to determine whether such an arch would be stable if built. The following example will illustrate the method of determining this.

Consider an unloaded semicircular arch of 20-ft span.

First, to find the depth of the keystone, we will use Rankine's Formula.

$$\text{Depth of key} = \sqrt{0.12 \times 10} = \sqrt{1.2} = 1.1 \text{ ft}$$

Trautwine's Formula gives nearly the same result,

$$\text{Depth of key} = \frac{\sqrt{10 + 10}}{4} + 0.2 \text{ ft} = 1.3 \text{ ft}$$

But if we should compute the stability of a 20-ft semicircular arch with a keystone 1.3 ft deep, we should find that the arch is very unstable; hence, in this case, we cannot use the formula and must act upon our own judgment. In the opinion of the author, the arch-ring of such an arch should be at least 2½ ft deep and the stability of the arch should be tested for that thickness. In all calculations on the arch, it is customary to consider it 1 ft thick at

* Taken from The Civil Engineer's Pocket-Book, John C. Trautwine.

right-angles to its face. This allows the AREAS OF THE FACES to be substituted for the ACTUAL WEIGHTS of the voussoirs and their loads. This method was used in the discussion of Retaining-Walls, Chapter IV, and Piers and Buttresses, Chapter VII. Furthermore, it is evident that if an arch 1 ft thick is stable, any number of arches of the same dimensions built alongside of it would be stable. In determining the stability of masonry arches it is also customary to neglect any increase in the strength of the arch from the mortar in the joints, or in other words, to consider the arch as laid up dry.

Graphic Determination of the Stability of Arches. An arch has already been defined as a particular arrangement of blocks of stone or other material, these blocks being called the VOUSSOIRS. For the sake of simplicity consider an UNLOADED ARCH. In such an arch each voussoir is subjected to the action of three forces, (1) the thrust that it receives from the voussoir next above it in the arch-ring, (2) the force of gravitation, or its own weight and (3) the reaction to the resultant thrust. The first two forces combine into one and form the thrust that this voussoir exerts on the one next below it in the arch-ring (Fig. 7). The points in which these various thrusts cut the joints are called the CENTERS OF PRESSURE of the joints, while the line joining these centers of pressure is called the LINE OF PRESSURE or LINE OF RESISTANCE.* In order that an arch may be absolutely stable, this line of resistance must fall within the MIDDLE THIRD of the arch-ring. (See Theorem of the Middle Third, Chapter IV.) If the arch is stable the centers of pressure on the various joint-lines are within the middle third of the voussoir-depths and the angles made by the different thrusts with the normals to the joints are less than the ANGLE OF FRICTION of the material of which the arch is constructed. If these conditions are not ful-

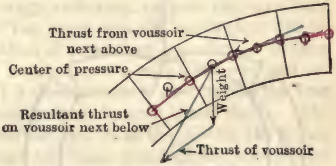

Fig. 7. Equilibrium of Forces on Voussoir

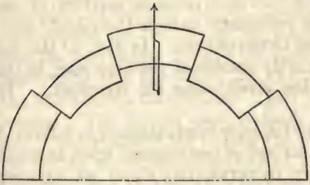

Fig. 8. Failure of Semicircular Arch. Haunches Sliding Down

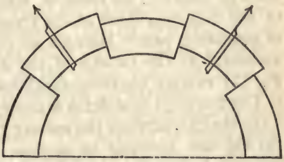

Fig. 9. Failure of Semicircular Arch. Haunches Sliding Up

filled the CRITERIA OF SAFETY, explained in Chapter VII in the discussion of the Stability of a Buttress, will not be satisfied; and at any joint where these conditions do not obtain, the voussoir above the joint will tend to SLIDE along the joint-plane if the angle made by the thrust with a normal to the joint is greater than the angle of friction. If the center of pressure lies outside the middle third, there will be a tendency for the voussoir to OVERTURN. When these tendencies reach extreme limits actual FAILURE may occur. Figures 8, 9, 10 and 11 illustrate some of the ways in which an arch may fail, Figs. 8 and 9,

* This line is called, interchangeably, the LINE OF PRESSURE, the LINE OF RESISTANCE, the RESISTANCE-LINE, etc.

showing different parts of the masonry sliding on the joints and Figs. 10 and 11 the failures caused by the passing of the line of pressure near the intrados or extrados.

Before passing to the actual discussion of the GRAPHIC METHOD for determining the stability of arches, a consideration of the action of the STRESSES developed in a construction of this kind will assist in a clearer understanding of the subject.

Fig. 8 shows how, if the line of resistance along the HAUNCHES of the arch should turn sharply downward and in so doing make with a normal to one of the joints an angle greater than the angle of friction, the voussoirs at this point

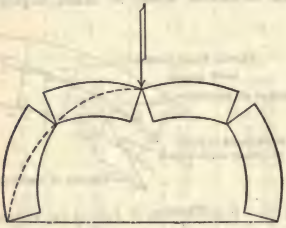

Fig. 10. Failure of Semicircular Arch. Opening of Arch-ring

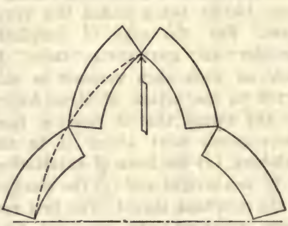

Fig. 11. Failure of Pointed Arch. Opening of Arch-ring

would tend to slide inward on their joint-planes, forcing outward the voussoirs at the spring and crown of the arch. Fig. 9 shows how failure of the arch would occur under similar conditions, but with the line of resistance turning sharply upward instead of downward. In these two cases it is conceivable that, although the RESISTANT THRUST at the joint where failure takes place makes an angle with the normal greater than the angle of friction, its point of application is still within the middle third of the joint.

Figs. 10 and 11, on the contrary, illustrate methods of failure in which, although the angle made by the thrust may be such as to cause no SLIPPING of one joint on another, its point of application is sufficiently outside the middle third of the arch-ring itself at the crown to cause OVERTURNING. In Fig. 10 the line of resistance passes high up, or perhaps entirely outside of the arch-ring, in the voussoirs at the CROWN of the arch and low down along the HAUNCHES. In Fig. 11 exactly contrary conditions exist.

The ten ways in which a masonry arch may fail have been classified as follows: * "(1) By CRUSHING of the masonry; (2) By SLIDING of one voussoir upon another; (3) By one voussoir or section of masonry OVERTURNING about an adjacent voussoir or section; (4) By SHEARING in a horizontal or vertical plane, this applying to solid concrete arches and not to voussoirs; (5) AS A COLUMN when the ratio of the unsupported length of an arch to its least width is greater than twelve; (6) From STRIKING THE CENTERING before the mortar is hard or when the arch, although stable under the full load, is not stable under its weight alone; (7) By STRIKING THE CENTERING or loading the arch during construction unsymmetrically; (8) By SETTLEMENT of the foundations; (9) By SLIDING upon the foundations; (10) By OVERTURNING about any point in the pier or abutment. Methods (8) and (9) are the most common ways of failure. All methods of failure, however, must be guarded against in design."

While some of these ways of failure may seem other than those illustrated in the foregoing figures, they may be perhaps more properly considered CAUSES

* W. J. Douglas in American Civil Engineering Pocket-Book, page 625.

OF FAILURE than WAYS OF FAILURE; and all, with the exception of the first, bring about a position of the line of resistance in the arch-ring which causes failure in one of the ways noted.

In regard to the method of failure (1), the conditions may be such that the loading, although symmetrical, is so excessive that although the line of resistance remains within the middle third, the total pressure on a joint is sufficient to CRUSH THE MATERIAL of which the arch is constructed. Such conditions, however, are not common.

From the foregoing discussion it is evident that in order to determine whether or not a given arch is stable, it is necessary to find the TRUE LINE OF RESISTANCE corresponding to the conditions of loading, form and dimensions of that particular arch. It is always possible, in every arch-ring, to pass one MAXIMUM and one MINIMUM LINE OF RESISTANCE. The TRUE LINE OF RESISTANCE will lie somewhere between these two. The method of procedure, therefore, is to pass tentatively, a line of resistance, either a maximum or a minimum one, and see if it remains within the middle third. If it does not, as it may not be the true line of resistance, it does not mean necessarily that the arch is not stable. The next step then, is to note where it departs farthest from the middle third, and to pass a second line of resistance through the same point on the crown-joint and the point on the line of the middle third where the original line departs farthest from the middle third. If this second line of resistance remains within the middle third it is reasonable to assume that the arch is stable. In these various operations it is only necessary to consider half the arch when the loading is symmetrical, and this is usually the case in architectural problems. The NUMBER OF VOUSSOIRS, also, into which we divide the half-arch, is immaterial and the joints need not coincide with those of the actual arch.

In order to pass a line of resistance through an arch-ring, the THRUST exerted by the other half AT THE CROWN-JOINT on the half-arch is first determined. This thrust is then combined with the resultant of the weight of the first voussoir and its load to determine the thrust exerted by this voussoir on the one next below it, and this thrust, in turn, is combined in the same way with the resultant of the weight and the load of the second voussoir, and so on down to the springing-joint, for each succeeding voussoir. The points in which the various lines representing the thrusts cut the joints are known as the CENTERS OF PRESSURE, and the line joining them is the LINE OF PRESSURE or LINE OF RESISTANCE. In performing this operation, the CENTER OF GRAVITY of each voussoir as well as the line passing through the center of gravity of the whole half-arch must be located. The face of each voussoir may be considered a TRAPEZOID, and any one of the methods for finding the center of gravity of this figure may be used for finding the center of gravity of each voussoir. The method of dividing the trapezoid into TRIANGLES is here employed and is shown at the side of the arch in Fig. 12. (See, also, Chapter VI, and VII, page 298.) As the determination of the position of the line passing through the center of gravity of the half-arch is the problem of finding the RESULTANT OF A SYSTEM OF PARALLEL FORCES, the method involving the drawing of the EQUILIBRIUM-POLYGON may be used. The most convenient way to determine the stability of an arch is to use the GRAPHIC METHOD. The STEPS in this method are outlined in the preceding paragraphs. Each of the operations will now be considered in detail.

First Step. Draw one-half the arch to as large a scale as convenient, and divide it into voussoirs of equal size. In the example shown in Fig. 12, the arch-ring is divided into ten voussoirs of equal face-areas. As already pointed out, it is not necessary that these should represent the actual voussoirs of which the arch is built. Next, the face-area of each of these voussoirs is to be found.

Where the arch-ring is divided into voussoirs of equal size, this is most easily done by computing the total area of the arch-ring and dividing this total area by the number of voussoirs. The FORMULA for finding the area of one-half the arch-ring is as follows:

$$\text{Area in square feet} = 0.7854\,(r^2 - r_1^2)$$

In this formula r is the outside radius and r_1 the inside radius in feet.

In this problem, for example, if the

$$\text{Area of the arch-ring} = 0.7854\,(12.5^2 - 10^2) = 44.2 \text{ sq ft}$$

as there are ten equal voussoirs, the area of each voussoir is 4.42 sq ft. Having drawn out one-half of the arch-ring, divide the crown-joint into three equal parts, and with radii of $O'E$ and $O'F$ describe the arcs dividing the arch-ring into thirds.

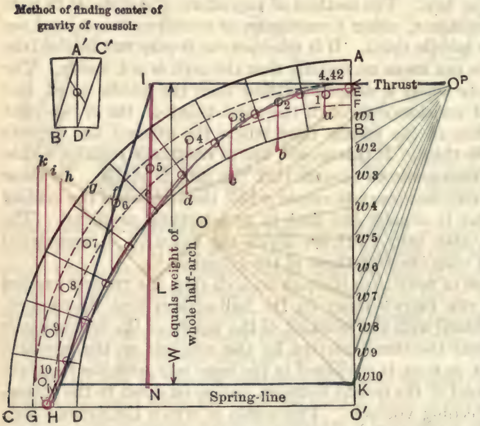

Fig. 12. Line of Pressure in Unloaded Semicircular Arch-ring

Second Step. Choose the points E and H through which to pass a MINIMUM LINE OF RESISTANCE. The points F and G, through which a MAXIMUM LINE OF RESISTANCE can be passed, could equally well have been chosen. It should be noted that an unloaded semicircular arch is more apt to fail by opening at the intrados at the crown and at the extrados at the spring, and therefore, in this case, the line of resistance probably passes nearer the OUTER THIRD at the CROWN and nearer the INNER THIRD at the SPRING. To determine this MINIMUM LINE OF RESISTANCE the MINIMUM THRUST, applied at the point E of the crown-joint, must first be determined.

The half-arch is in equilibrium under the action of three forces: (1) the THRUST AT THE CROWN, acting horizontally, applied at the point E and preventing the half-arch from overturning inward; (2) the WEIGHT OF THE HALF-ARCH considered as a vertical force, acting through its center of gravity and tending to overturn it inwards about the point D; and (3) A FORCE EQUAL AND OPPOSITE TO THE RESULTANT of these two forces and passing from H to I. I is the intersection of the weight-line through the center of gravity of the half-arch, with the line of action of the thrust at the crown, prolonged. It is thus possible to construct the TRIANGLE OF THESE THREE FORCES and determine the magnitudes of the thrusts, when the position of the weight-line of the half-arch is determined. It is first necessary to draw a vertical line through the center of gravity of each voussoir. The center of gravity of one of the voussoirs may be found by the METHOD OF TRIANGLES, as shown in the supplementary figure at the side of the arch-ring.

Having determined the positions of the centers of gravity of the voussoirs,

locate them on the voussoirs as shown. From the point E (Fig. 12) lay off vertically, to a scale of so many SQUARE UNITS TO A LINEAR UNIT, the area of each voussoir, one below the other, commencing with the top voussoir. The length of the line EK will then equal the total area of the arch-ring. From E and K (Fig. 12) draw 45° lines intersecting at O. Draw Ow 1, Ow 2, Ow 3, etc. Then where OE intersects the first vertical line through the center of gravity of the first voussoir at a, draw a line parallel to Ow 1, intersecting the second vertical at b. Draw bc parallel to Ow 2, cd parallel to Ow 3 and so on to k. Draw kL parallel to Ow 10 and prolong it downward until it intersects EO prolonged, at L. A vertical line drawn through L will pass through the center of gravity of the half arch-ring. This is an application to a practical problem of the method of finding, by the EQUILIBRIUM-POLYGON, the line of action of the resultant of a SYSTEM OF PARALLEL FORCES. The weights of the individual voussoirs act along parallel vertical lines and the weight of the half-arch is their resultant in magnitude.

Third Step. To determine the THRUST AT THE CROWN and the REACTION AT THE SPRING, draw a horizontal line through E, the upper part of the middle third, and a vertical line through L, the two lines intersecting at I (Fig. 12). For the arch to be stable, it is, in general, considered necessary for the LINE OF RESISTANCE to pass within the MIDDLE THIRD. First, assume that the line of pressure or resistance starts at E and comes out at H. Draw a line IH the direction of the line of action of the resultant of the thrust at the crown and the weight of the half-arch, and draw, also, a horizontal line opposite the point w 10, between N and M. This horizontal line MN represents the magnitude of the horizontal thrust at the crown, for INM is the TRIANGLE OF THE THREE FORCES in equilibrium, the THRUST at the crown, the WEIGHT of the half-arch and the REACTION at the spring. Draw w 10 O^p parallel to HI, and the lines O^pw 1, O^pw 2, O^pw 3, etc. O^pE, equal to NM, is the thrust at the crown, and w 10 O^p, equal to MI, the reaction at the spring. INM and EKO^p are similar triangles.

Fourth Step. It is required next, to determine the LINE OF RESISTANCE through the arch-ring. The thrust at E is combined with the weight of the first voussoir; their resultant is found and in turn combined with the weight of the second voussoir; and so on for all the voussoirs. The intersections of these resultants with the joint-lines are the CENTERS OF PRESSURE; the line joining these centers of pressure is the LINE OF RESISTANCE.

These resultants could be determined by drawing a series of PARALLELOGRAMS OF FORCES over each voussoir. This would complicate the figure and involve unnecessary labor. It is found more convenient to draw the TRIANGLES OF FORCES one after the other, at the right-hand side of the figure and then transfer the results thus obtained by means of parallel lines to the figure itself, especially as the weights of the voussoirs have already been laid off along the line EK, at Ew 1, w 2, w 3, w 4, w 5, etc.

Then from the point where O^pE prolonged intersects the first vertical in voussoir number 1, draw a (green) line to the second vertical, parallel to O^pw_1; from this point, a (green) line to the third vertical, parallel to O^pw 2 and so on. The last line should pass through H. Join the various points, where these (green) lines cut the joints at the centers of pressure, by the broken (red) line. This last line drawn is the LINE OF RESISTANCE. If this line lies entirely within the MIDDLE THIRD of the arch-ring, the arch may be considered to be stable. But suppose that the line of resistance passes not only outside of the middle third but also outside of the arch-ring itself; it is still possible that the arch is not unstable. This is the case in Fig. 12 and we will next determine if a

line of resistance can be drawn which will remain within the limits of the middle third of the arch-ring.

Fifth Step. The Second Trial. Reproducing the condition of Fig. 12 in Fig. 13, without the construction lines, it is seen that the LINE OF RESISTANCE leaves the arch-ring at R and enters it again at S, while it is furthest from it at U. If, at U, a perpendicular is erected to a straight line joining the two points R and S, this perpendicular line VW, called the LINE OF FRACTURE, will be approximately the trace of the plane along which, with the line of resistance under consideration, the arch will tend to fail, presumedly by TURNING OVER to the right about the point V. This shows that the THRUST AT THE CROWN, assumed to be applied at the point E, while of sufficient intensity to maintain equilibrium about H, is not of sufficient intensity to maintain equilibrium about V. If now a SECOND THRUST, of sufficient intensity to maintain equilibrium about V, or better, about X, can be applied at E without being so great in magnitude that it will OVERTURN THE ARCH OUTWARD about G, or some other point on the outer line of the middle third, it

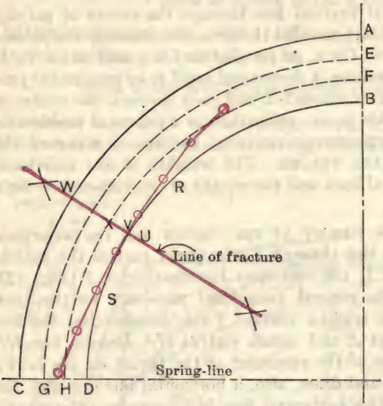

Fig. 13. Line of Fracture in Unloaded Semicircular Arch-ring

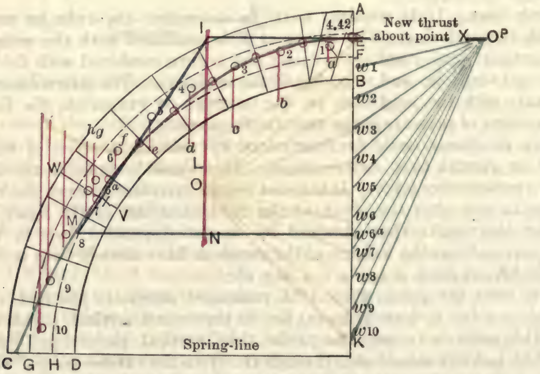

Fig. 14. Second Line of Pressure in Unloaded Semicircular Arch-ring

is reasonable to conclude that the line of resistance resulting from this thrust is very nearly the TRUE LINE OF RESISTANCE in the arch-ring and that the arch is stable.

In order to determine this NEW LINE OF RESISTANCE the NEW THRUST AT THE

CROWN must be found (Fig. 14). The preliminary steps required for this are the same as before until the seventh voussoir is reached. This is divided into two voussoirs by the line VW (Fig. 14), one being $w6\ w6^a$ and the other the remainder of this seventh voussoir, and this division must be allowed for along the load-line EK, at $w6\ w6^a$. The line $w6\ w6^a$ represents the area of voussoir 6^a, and the line $w6^a\ w7$ the area of the remainder of the seventh voussoir.

The vertical line IL, passing through the center of gravity of that part of the half-arch above the line VW, is found by prolonging backwards the line hg, parallel to $O\,w6^a$, until it intersects OE at L. To find the NEW THRUST AT THE CROWN by completing the TRIANGLE OF FORCES for this thrust and the force equal and opposite to their resultant, the inclined (blue) line must be drawn through the point X and the horizontal (blue) line through $w6^a$. The new thrust then is as before NM, equal to O^pE. This thrust is laid off at O^pE, the (green) lines O^pw 1, O^pw 2, O^pw 3, etc., being drawn as before and the new line of resistance being drawn through the points where the parallels to these (green)

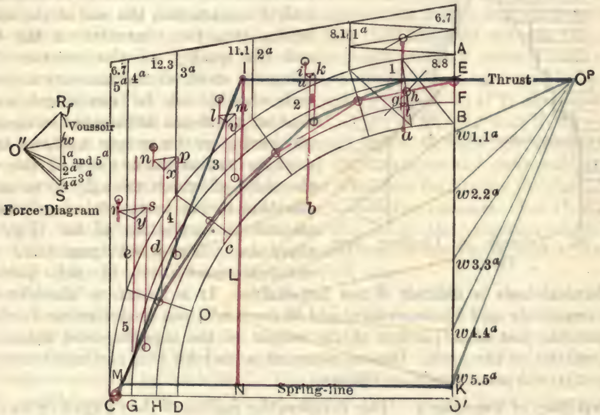

Fig. 15. Line of Pressure in Loaded Semicircular Arch-ring

lines cut the joints. This NEW LINE OF RESISTANCE, if drawn correctly, should pass through X. It lies within the middle third, except for a short distance at the springing, and hence it is justifiable to consider the arch stable. If it had passed outside the middle third to any great extent, in this second trial, this presumption would not have been justified.

This discussion explains the method of determining the stability of an UNLOADED SEMICIRCULAR ARCH. Such cases very seldom occur in practice, but they serve to illustrate the methods which apply generally to all other cases. With LOADED ARCH-RINGS there is slight difference in the method of determining the position of the center of gravity.

Example 3. A LOADED OR SURCHARGED SEMICIRCULAR ARCH (Fig. 15) will be considered next. Assume the same arch shown in Figs. 12, 13 and 14, and suppose it to be loaded with a wall of masonry of the same thickness and weight per square foot as that of the arch-ring, the upper surface of the wall being an inclined plane, 1 ft above the arch-ring at the crown, and 8 ft above it at the spring. The assumption of the particular load in this case is a purely arbitrary

one for the purpose of illustrating the method of solution. The determination of the ACTUAL LOAD that comes upon an arch in any given case is by no means easy, so numerous are the uncertain elements that affect the transmission of this load to the arch-ring.

The customary procedure is to assume that the load is itself transmitted to the arch-ring VERTICALLY DOWNWARD. Each voussoir thus receives that portion of the load which is included between two vertical lines drawn to the points of intersection of the joints on either side of that voussoir with the extrados. Having made this assumption it is necessary next to determine how much of the total superimposed masonry bears upon the arch-ring.

It is a matter of common observation that if an opening is made in a wall, especially in a wall that has stood for some time, the major portion of the masonry above this opening is self-supporting, limited portions only, bounded by a somewhat irregular line, falling down into the opening, as shown in Fig. 16. The profile of this boundary-line depends upon the nature of the material of which the wall is constructed, the size of the stones, bricks, etc., the character of the bond and the quality of the mortar. This being the case, all the masonry above an arch should not be considered as the load on it. Some authorities recommend considering as the proper load, for brickwork, a TRIANGULAR PART of the wall, the sides of which triangle have an inclination to the horizontal of 45°; others assume an inclination of 60° (Fig. 16). (See, also, Chapter XV, page 612.) The exact determination of this load by mechanical laws is difficult if not impossible. It is better to consider each case separately and by a careful study of the conditions to determine as closely as possible just what portion of the weight of the superimposed masonry is transmitted to the arch. Having assumed a load for this particular arch-ring (Fig. 15), the procedure is as follows:

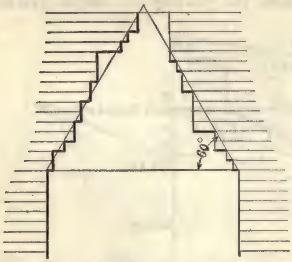

Fig. 16. Triangle of Loading over Opening

First Step of Example 3. This involves the finding of the CENTER OF GRAVITY of the ARCH-RING AND LOAD COMBINED. Divide the arch-ring into five voussoirs of equal size. In this case the area of each voussoir is equal to 44.2 sq ft ÷ 5, or 8.8 sq ft. (See under First Step, Fig. 12, preceding example.) The surcharge or load, also, is divided into five parts, not necessarily equal, by drawing vertical lines to the points of intersection of the joints and the extrados. The approximate area of each one of these surcharges is found by multiplying half the sum of the lengths of the two parallel vertical sides by the length of the horizontal distance between them.

The positions of the center of gravity of each voussoir and of the center of gravity of each voussoir-surcharge are determined as in the preceding example. The CENTERS OF GRAVITY of these SURCHARGES can be found by dividing each TRAPEZOIDAL FIGURE into TRIANGLES as shown, remembering that the MEDIAL LINE in this case joins the middle points of the two parallel faces. As the latter are vertical, the medial lines approach a horizontal direction. This construction is shown on surcharge 1^a, Fig. 15. Having drawn the lines of action of the weights of the various voussoirs and of their loads through their respective centers of gravity, the lines of action of the combined weight of each voussoir and its load must be found. The construction for this operation is shown at

the left of Fig. 15. The method used, that of the EQUILIBRIUM-POLYGON, is the same as that employed in the previous example to find the line passing through the center of gravity of the half-arch, only in this case the forces are reduced to two. Furthermore, as the areas of the various voussoirs are equal it is possible to superimpose the different FORCE-DIAGRAMS, one over the other, and so save considerable labor. Begin, therefore, by laying off along the line RS at the left of the loaded arch, and at any convenient scale, fw, the area (weight) of a voussoir; then from w, in turn, the distances $w\ 1^a$, $w\ 2^a$, $w\ 3^a$, etc., representing the areas of the successive surcharges, 1^a, 2^a, 3^a, etc., always at the same scale. The scale to be employed later for laying off the combined weights of the voussoirs and their loads along the line AK is the best one to choose, but the difference in scales is not important. In this particular instance the two points 1^a and 5^a coincide because the two areas 1^a and 5^a, although of different shapes, are each equal to 6.7 sq ft. This is a mere coincidence. Next draw fO'' and $4^a\ O''$ at 45° to RS, and in turn, $O''w$, $O''1^a$, $O''2^a$, etc. As the problem which presents itself is to combine the weight of each voussoir with its individual surcharge, and as the weights of all the voussoirs are equal, and, furthermore, as the forces which are to be combined to find their resultant are only two, the two POLE-LINES OF RAYS $O''f$ and $O''w$ in the FORCE-DIAGRAM serve in each case, and the FUNICULAR POLYGON is reduced to a TRIANGLE. Draw gh, ik, lm, np and rs parallel to $O''w$, and ht, ku, mv, px and sy parallel to $O''f$; and draw gt, iu, lv, nx and ry parallel respectively to $O''1^a$, $O''2^a$, $O''3^a$, $O''4^a$ and $O''5^a$. The points t, u, v, x and y are the points through which to draw the heavy (red) lines of action of the combined weights of the voussoirs and their surcharges.

Having found and drawn these lines, the procedure for finding the line IN is the same as in the previous example, except that the distances $Ew1\ 1^a$, $w1\ 1^a$, $w2\ 2^a$, etc., instead of being equal to the weights of the voussoirs alone, are equal to the combined weights of each voussoir and its surcharge, $Ew1\ 1^a$, being equal to $f\ 1^a$, $w1\ 1^a$ to $w2\ 2^a$ being equal to $f\ 2^a$, etc.

The line EO is drawn at 45° to AO', but as the position of the POLE-POINT, O, is entirely arbitrary, the line $Ow\ 5\ 5^a$ has been drawn in this case in such a way that O falls well over toward the left of the figure, thus avoiding a certain amount of confusion in the drawing which would have resulted if $Ow\ 5\ 5^a$ had made an angle of 45° with AO'. The lines ab, bc, cd and de are drawn respectively parallel to $w1\ 1^aO$, $w2\ 2^aO$, etc., and eL is produced backward parallel to $Ow\ 5\ 5^a$ until it intersects EO at L, which is the point through which the heavy (red) line IN, passing through the center of gravity of the whole half-arch and its surcharge, should be drawn. A vertical line drawn through L will pass through the center of gravity of the arch-ring and its load. If this were an arch designed for a building and if the only abutments possible were of such size and form that it was essential for the thrust exerted by the last or fifth voussoir on these abutments to approach more nearly the vertical, the architectural expedient of increasing slightly the weight of the surcharge, 5^a, on this voussoir by adding some piece of ornament, such as a cartouche, could be resorted to. A case of this kind in actual practice is the archway over the entrance to the service-courtyard of the Grand Opera House in Paris, where the pyramidal stone ornaments which surmount the cornice on either side of the central motive were added after the original design was made, with this end in view. In the example illustrated in Fig. 15 the areas of the faces of the surcharges are shown by the figures on these faces. For the second surcharge from the crown, for example, the area is 8.1 sq ft.

Second Step of Example 3. This involves the determination of the THRUST AT THE CROWN and the LINE OF RESISTANCE. The method of finding this thrust

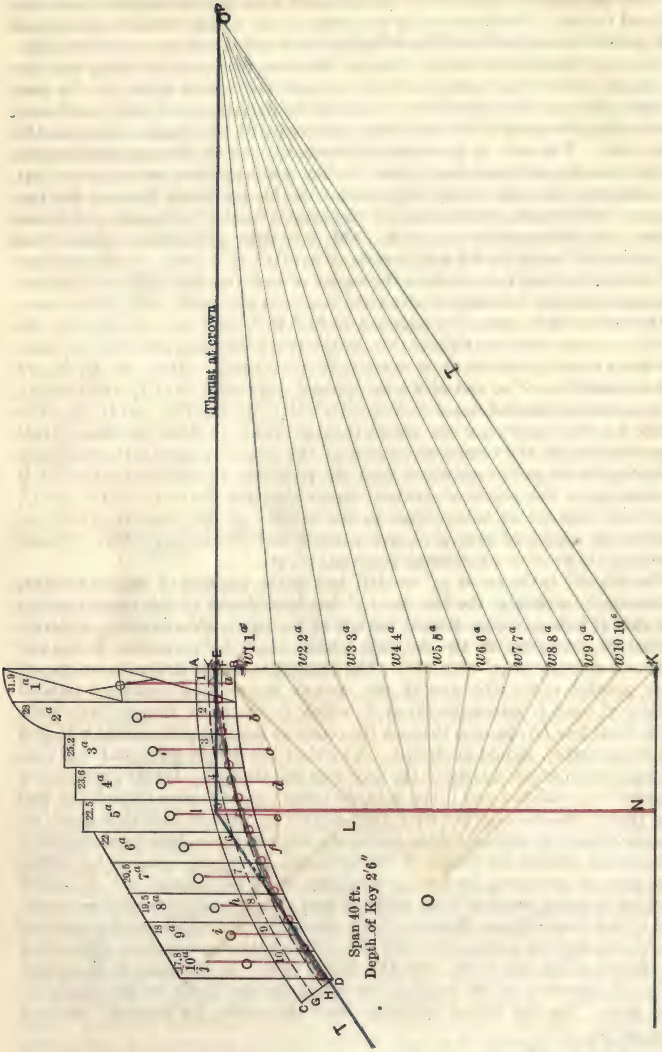

Fig. 17. Line of Pressure in Loaded Segmental Arch-ring

at the crown is similar to that employed in the previous example. In that example, however, it was found that this thrust, applied at E and determined by assuming H as the point of application of the reaction at the spring, produced a line of resistance which fell considerably below the middle third. But instead of performing the operations required by a second trial, as in the previous example, the expedient is tried of slightly increasing the inclination to the vertical of the (blue) line IM, and so assuming a somewhat greater THRUST AT THE CROWN. As the line of resistance, as shown in Fig. 15, passed with this thrust departs but slightly from the middle third near the springing, we are justified in assuming that this arch is stable under the given conditions. The method used for this example may be used, also, for a SEMIELLIPTICAL ARCH.

Example 4. This example (Fig. 17) illustrates the application of the preceding methods, with some variations, to the determination of the position of the center of gravity of a LOADED SEGMENTAL ARCH, the thrusts at the crown and spring and the line of pressure or resistance through the arch-ring. In this case, instead of dividing the arch-ring into a certain number of voussoirs with joints radiating from a center and considering the surcharge on each individual voussoir, the method of dividing the arch-ring and its load into VERTICAL SLICES, in this case two feet wide, and computing the areas of the entire slices has been adopted. Having computed the areas of the slices, including in each case the combined areas of the sliced part of the arch-ring and its surcharge, we lay them off in order from E, to a convenient scale, and then proceed as in the previous examples. The remaining steps required to determine the thrusts at the crown and at the spring and the line of resistance are also the same as explained in the foregoing paragraphs. In a FLAT SEGMENTAL ARCH there is practically no need of dividing the arch-ring into voussoirs by JOINTS RADIATING FROM A CENTER, in order to determine its stability. Of course, when built, they must be made to radiate.

Fig. 17 shows the GRAPHICAL ANALYSIS of an arch of 40-ft span and carrying a load 13½ ft high at the crown. The depth of the arch-ring is 2 ft 6 in. It is seen that the line of resistance lies entirely within the middle third, and that the arch is therefore stable. It is to be noted that the line of resistance in a SEGMENTAL ARCH should be drawn through the LOWER OF INNER EDGE of the middle third at the springing. It is to be noted, also, that the horizontal thrust at the crown and the thrust T against the supports are very great when compared with those in a SEMICIRCULAR ARCH; and hence, although the SEGMENTAL ARCH is the stronger of the two, it requires much heavier abutments. The foregoing examples serve to show the various methods of determining the stability and thrusts of any arch used in buildings.

Reinforced-Concrete Arches. Many arches are now built of concrete reinforced by steel ribs. Such arches, however, are much more common in civil engineering than in architectural structures and so hardly come within the province of an architect's handbook. Many comprehensive and practical papers, however, on such arches have been published in recent engineering literature.

CHAPTER IX

REACTIONS AND BENDING MOMENTS FOR BEAMS

By

CHARLES P. WARREN

ASSISTANT PROFESSOR OF ARCHITECTURE, COLUMBIA UNIVERSITY

1. Reactions for Beams

Definition of Reaction. One of the fundamental principles of static equilibrium is that the sum of all the forces acting upon a body in one direction must be balanced by the sum of another set of forces acting in the opposite direction. Therefore, in the case of a beam or girder, the loads acting downward must be balanced by an equal set of forces at the supports, acting upward. These upward forces are called THRUSTS, or REACTIONS and in computing the strength of beams one of the first steps is to determine them, since the loads are usually given in intensity and position.

The Principle of Moments. The reactions may be determined by the application of another fundamental principle of static equilibrium for forces acting in the same plane. The algebraic sum of the moments of all the forces

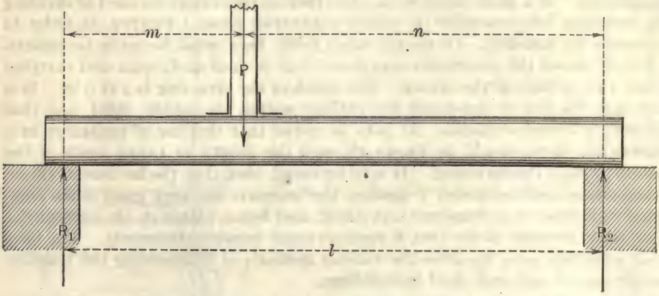

Fig. 1. Simple Beam. One Concentrated Load

taken about any point in the plane in which they act must be zero. The MOMENT OF A FORCE about a point is the product of the magnitude or intensity of the force by the perpendicular distance between the LINE OF ACTION of the force and the point. The perpendicular distance is called the LEVER-ARM, and the point the CENTER OF MOMENTS. Forces acting upward are considered POSITIVE and those acting downward are considered NEGATIVE. The center of moments may be taken at any point in the plane of action of the forces, but it is more convenient to take it at one of the reactions. For example, the beam in Fig. 1 supports a concentrated load P at the distance m from the left support. To find the left reaction take the center of moments at the right reaction. Then the EQUATION OF MOMENTS is

$$R_1 l - Pn = 0.$$

from which

$$R_1 = Pn/l \qquad (1)$$

In like manner, to find R_2 the center of moments is taken at R_1 and the equation of moments is

$$R_2l - Pm = 0, \text{ from which } R_2 = Pm/l \qquad (1)'$$

From the first principle of statics mentioned, $R_1 + R_2$ must equal P; hence, as a check, $Pn/l + Pm/l = P$.

Example 1. Let a beam 15 ft in span support a concentrated load of 700 lb, 6 ft from the left end; or, $P = 700$, $m = 6$ and $n = 9$. Then, from Formula (1), $R_1 = 700 \times 9/15 = 420$ lb. $R_2 = 700 \times 6/15 = 280$ lb and $420 + 280 = 700$ lb.

For a concentrated load at the middle, or for a uniform load over a simple beam, it is evident without applying the conditions of equilibrium, that each reaction is one-half the load, for, in Formulas (1) and (1)′, m and n each equal $l/2$ and R_1 and $R_2 = \frac{1}{2} P$.

For any number of concentrated loads (Fig. 2) the reactions may be found by adding together the reactions found by Formula (1) due to each load separately, or they may be computed in one operation by the following formula:

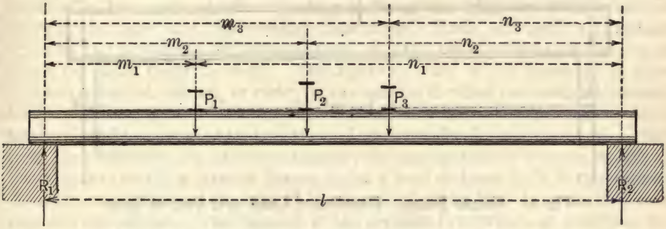

Fig. 2. Simple Beam. Three Concentrated Loads

To find the right reaction, the center of moments is taken at the left support, and the equation of moments is

$$R_2l - P_1m_1 - P_2m_2 - P_3m_3 = 0$$

hence,

$$R_2 = \frac{P_1m_1 + P_2m_2 + P_3m_3}{l} \qquad (2)$$

In like manner, to find R_1 the center of moments is taken at R_2 and the equation of moments is

$$R_1l - P_1n_1 - P_2n_2 - P_3n_3 = 0$$

from which

$$R_1 = \frac{P_1n_1 + P_2n_2 + P_3n_3}{l} \qquad (3)$$

Example 2. Suppose the beam in Fig. 2 is 20 ft in length. Let there be three concentrated loads of 500, 800 and 600 lb placed 5, 9 and 12 ft respectively from the left support. Then $l = 20$, $m_1 = 5$, $m_2 = 9$, $m_3 = 12$, $P_1 = 500$, $P_2 = 800$ and $P_3 = 600$. Substituting in Formulas (2) and (3),

$$R_2 = \frac{500 \times 5 + 800 \times 9 + 600 \times 12}{20} = 845 \text{ lb}$$

$$R_1 = \frac{500 \times 15 + 800 \times 11 + 600 \times 8}{20} = 1\,055 \text{ lb}$$

and

$$500 + 800 + 600 = 845 + 1\,055 = 1\,900 \text{ lb}$$

To find the reactions for a combination of uniformly distributed and concentrated loads, to each of the reactions obtained by Formulas (1) or (2) for the concentrated loads, add one-half the distributed load. Thus, suppose the 20-ft beam in this example weighs 40 lb per linear ft. This is considered as a uniformly distributed load and for the entire beam it is 40 lb × 20 = 800 lb. By the rule, one-half of this is added to each reaction, so that the total reactions are, $R_1 = 845 + 400 = 1\ 245$ lb and $R_2 = 1\ 055 + 400 = 1\ 455$ lb.

Example 3. For a distributed load applied over only a part of the span, as in Fig. 3, assume the load to be CONCENTRATED AT THE MIDDLE of the part over

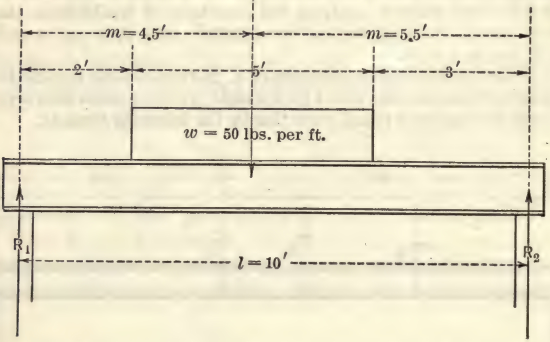

Fig. 3. Simple Beam. Distributed Load over Part of Span

which it acts and use Formulas (1) and (1)′. For example, let w (Fig. 3) equal 50 lb per linear ft, applied for a distance of 5 ft over the beam. Then W, the total load, is 50 lb × 5 = 250 lb. This may be assumed to be concentrated at its center, 4.5 ft from the left support. Then $P = 250$, $m = 4.5$ and $n = 5.5$; and from Formulas (1) and (1)′,

$$R_1 = \frac{250 \times 5.5}{10} = 137.5 \text{ lb}$$

and

$$R_2 = \frac{250 \times 4.5}{10} = 112.5 \text{ lb}$$

Therefore, for any combination of concentrated and uniform loads distributed over the entire beam, or over only part of it, find the reactions due to the concentrated loads by Formulas (1) or (2), and to them add the reactions due to the uniformly distributed loads.

2. Bending Moments in Beams *

Definitions. The bending moment is a measure of the tendencies of forces to break a beam by BENDING OR FLEXURE. Fig. 4 shows the manner in which a simple beam, supported at the ends, breaks when subjected to a load greater than it can bear. The effect of a load upon a beam is to cause it to SAG, or BEND. The bending of the beam shortens, or compresses, the upper fibers and stretches, or elongates, the lower fibers. So long as the resistance of the fibers

* See, also, Chapter XV, pages 555 to 563.

to shortening, or compression, and to stretching, or tension, is greater than the tendency of the load to disrupt them, the beam carries the load; but, when the load causes a greater tension, or compression, on the fibers than they are capable of resisting, the beam breaks. The stretching of the fibers before breaking allows the beam to bend; hence, the name BENDING MOMENT has been given to the forces causing a beam to BEND and perhaps ultimately to BREAK.

Fig. 4. Manner of Rupture of Simple Beam

In order to calculate the FLEXURAL STRENGTH OF A BEAM, it is necessary to ascertain the nature and extent, first, of the EXTERNAL FORCES acting to break the beam, and secondly of the INTERNAL FORCES or STRESSES tending to resist rupture.* The external forces tending to break the beam by flexure are the DOWNWARD LOADS and the UPWARD REACTIONS. Each acts with a LEVERAGE equal to the perpendicular distance from its LINE OF ACTION to the section at which the beam tends to break. The algebraic sum of the moments of these external forces on the left, or right, of any section is called the BENDING MOMENT for that section, since it is the MOMENT OF THE RESULTANT OF THE FORCES which tends to bend the beam at that section. It is generally designated by M. Then, from the definition, the BENDING MOMENT for any section of a beam resting on two supports and in a state of flexure under a load or loads is M = the moment of either reaction minus the sum of the moments of the loads between that reaction and the section. The moment of the reaction is UPWARD, or POSITIVE, and the moment of any load DOWNWARD, or NEGATIVE, if the part of the beam on the left of the section is considered.

3. Bending Moments in Beams for Different Kinds of Loading

Case I

Beam Fixed at One End and Loaded with a Concentrated Load *P*, Near the Free End (Fig. 5).

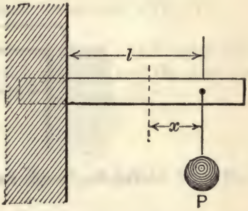

Fig. 5. Cantilever Beam. Concentrated Load near Free End

Maximum bending moment, at wall $= P \times l$
Bending moment at any other section $x = Px$

Note. If l is in feet, the bending moment will be in foot-pounds; if l is in inches, the bending moment will be in inch-pounds.

Case II

Beam Fixed at One End and Loaded with a Uniformly Distributed Load *W*. (Fig. 6.)

Maximum bending moment, at wall $= W \times l/2$
At any other section x, $M = wx \times x/2 = wx^2/2$

Note. $W = wl$ and $w =$ the load per unit of length.

* See Chapter X for a discussion of these internal stresses and of the resisting moment.

Case III

Beam Fixed at One End and Loaded with Both a Concentrated and a Uniformly Distributed Load (Fig. 7).

Maximum bending moment, at wall $= P \times l_2 + W \times l_1/2$

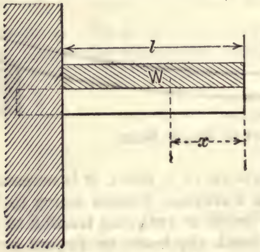

Fig. 6. Cantilever Beam. Uniformly Distributed Load

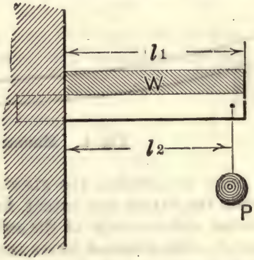

Fig. 7. Cantilever Beam. Distributed Load and Load at Free End

Case IV

Beam Supported at Both Ends and Loaded with a Concentrated Load at the Middle (Fig. 8).

Maximum bending moment, under the load $= Pl/4$

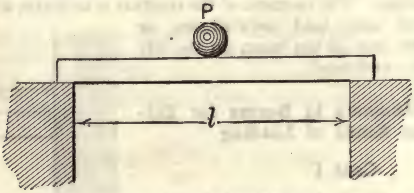

Fig. 8. Simple Beam. Concentrated Load at the Middle

Case V

Beam Supported at Both Ends and Loaded with a Uniformly Distributed Load *W* (Fig. 9).

Maximum bending moment, at the middle $= Wl/8$

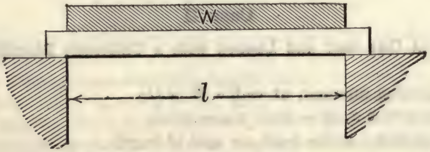

Fig. 9. Simple Beam. Uniformly Distributed Load

Case VI

Beam Supported at Both Ends and Loaded with a Concentrated Load not at the Middle (Fig. 10).

Maximum bending moment, under the load = Pmn/l

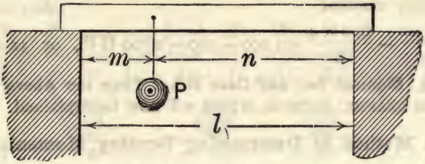

Fig. 10. Simple Beam. Concentrated Load not at the Middle

Case VII

Beam Supported at Both Ends and Loaded Symmetrically with Two Equal Concentrated Loads (Fig. 11).

Maximum bending moment = Pm and is the same for any section of the beam between the two loads.

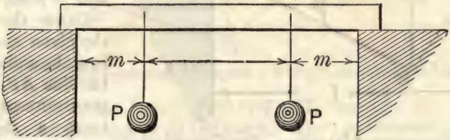

Fig. 11. Simple Beam. Two Concentrated Loads Symmetrically Placed

From these examples it will be seen that all the quantities which enter into the computation of the bending moment are the load, the span and the distance of the point of application of the load from the center of moments.

Case VIII

Beam Supported at Both Ends and Loaded with a Distributed Load Over Part of the Span (Fig. 12).

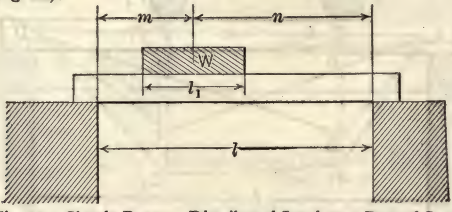

Fig. 12. Simple Beam. Distributed Load over Part of Span

If assumed under the center of the load, $M^*_{\max} = Wmn/l - Wl_1/8$

When m and n are equal the bending moment $= W \times l/4 - W \times l_1/8$

* This is only approximately correct when m and n are unequal. For the exact value, find the section of zero shear; the maximum bending moment will be at that section.

Example 4. In Fig. 12 let $W = 800$ lb, $m = 8$ ft, $n = 12$ ft, $l = 20$ ft and $l_1 = 8$ ft. Then the bending moment

$$= \frac{800 \times 8 \times 12}{20} - \frac{800 \times 8}{8} = 3\,840 - 800 = 3\,040 \text{ lb, or } 36\,480 \text{ in-lb}$$

Example 5. In Fig. 12 let $m = n = 10$ ft, $l = 20$ ft, $l_1 = 4$ ft and $W = 600$ lb. Then the bending moment

$$= \frac{600 \times 20}{4} - \frac{600 \times 4}{8} = 3\,000 - 300 = 2\,700 \text{ ft-lb, or } 32\,400 \text{ in-lb}$$

The Bending Moment for any Case Other Than the Above may easily be obtained by the GRAPHIC METHOD, which will now be explained.

4. Graphic Method of Determining Bending Moments in Beams

Beam with One Concentrated Load (Fig. 13).

The BENDING MOMENT of a beam supported at both ends and loaded with one concentrated load may be determined GRAPHICALLY, as follows:

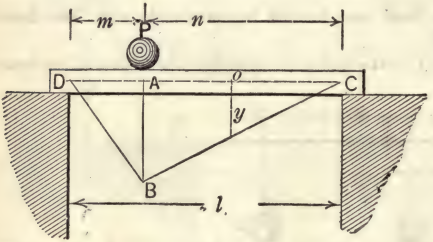

Fig. 13. Bending-moment Diagram. One Concentrated Load

Let P be the load, applied as shown. Then, by the rule under Case VI, the MAXIMUM BENDING MOMENT is under the load and $= Pmn/l$

Draw the beam, with the given span, accurately to scale, and measure down the line AB, to a scale of FOOT-POUNDS to the LINEAR INCH, a distance equal to the bending moment. Connect B with each end of the beam. To find the bending moment at any other point of the beam, as at o, draw the vertical line y to BC. Its length, measured to the same scale to which AB is drawn, will give the bending moment at o. The figure $DBCAD$ is called the BENDING-MOMENT DIAGRAM and the lines BD and BC are called INFLUENCE LINES for the bending moments.

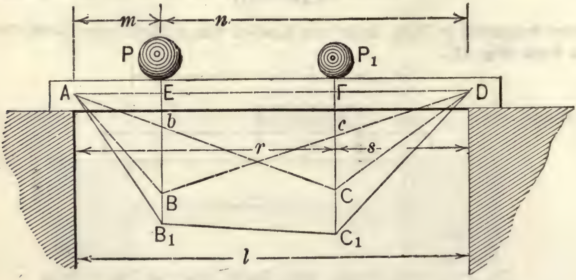

Fig. 14. Bending-moment Diagram. Two Concentrated Loads

Beam with Two Concentrated Loads (Fig. 14).

To draw the bending-moment diagram for a beam with two concentrated loads, draw the dotted lines ABD and ACD, giving the BENDING-MOMENT DIA-

GRAMS for each load separately. EB is laid out to scale, equal to Pmn/l and FC equal to P_1rs/l

The bending moment at the point E is equal to EB (from the load P) $+ Eb$ (from the load P_1), or $M = EB + Eb = EB_1$; and at F the bending moment is equal to $FC + Fc = FC_1$. The BENDING-MOMENT DIAGRAM for both loads is AB_1C_1D and the MAXIMUM BENDING MOMENT is, in this particular case, the line FC_1 measured to scale.

Beam with Three Concentrated Loads (Fig. 15).

Proceed as in the last case, and draw the BENDING-MOMENT DIAGRAM for each load separately. Make $AD = A1 + A2 + A3$, $BE = B1 + B2 + B3$ and

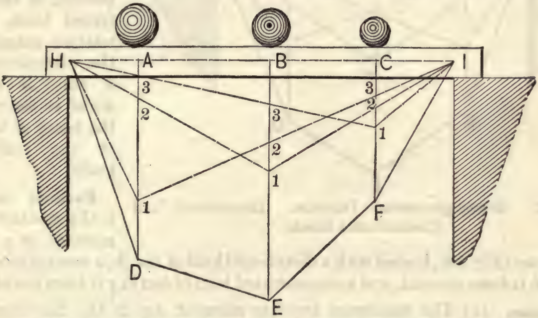

Fig. 15. Bending-moment Diagram. Three Concentrated Loads

$CF = C1 + C2 + C3$. The figure $HDEFIH$ will then be the BENDING-MOMENT DIAGRAM corresponding to all the loads. The BENDING-MOMENT DIAGRAM for a beam with any number of concentrated loads may be drawn in the same way.

Beam with a Uniformly Distributed Load (Fig. 16).

Draw the beam with the given span, accurately to a scale as before, and at the middle of the beam draw the vertical line AB, to a scale of a certain number of FOOT-POUNDS to the LINEAR INCH, equal to $Wl/8$, from Case V, W representing the whole distributed load. Connect the points C, B, D by a PARABOLA to obtain the BENDING-MOMENT DIAGRAM. To find the bending moment at any point a, draw the vertical line ab, measure it to the same scale to which AB is drawn, and it will be the bending moment desired. Methods for drawing the PARABOLA will be found in Part I, page 79.

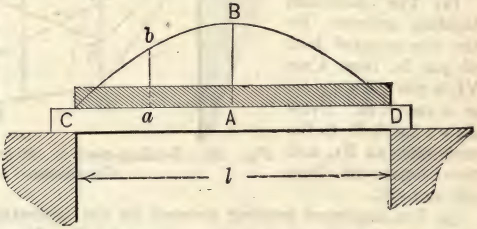

Fig. 16. Bending-moment Diagram. Distributed Load over Whole Beam

Beam Loaded with Both Distributed and Concentrated Loads (Fig. 17).

To determine the bending moments in this case, combine the BENDING-MOMENT DIAGRAMS for the concentrated loads and for the distributed load, as shown in

Fig. 17. The bending moment at any section of the beam will then be limited by the line ABC on top and by the line $CDEFA$ on the bottom; and the MAXIMUM BENDING MOMENT will be the longest vertical line that can be drawn between these two bounding lines.

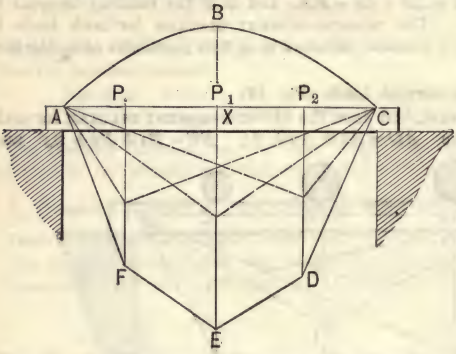

Fig. 17. Bending-moment Diagram. Distributed and Concentrated Loads

For example, the bending moment at X is BE. The point of MAXIMUM BENDING MOMENT depends upon the position of the concentrated loads and the relative magnitude of the distributed load; it may or may not occur at the middle of the beam or under one of the concentrated loads.

Example 6. What is the greatest bending moment in a beam of 20 ft span (Fig. 18), loaded with a distributed load of 800 lb, a concentrated load of 500 lb 6 ft from one end, and a concentrated load of 600 lb 7 ft from the other end?

Solution. (1) The maximum bending moment due to the distributed load, from Case V, is $Wl/8$, or $800 \times 20/8 = 2\,000$ ft-lb. Lay off vertically over the middle of the beam, and at any convenient scale, say 4 000 ft-lb to the inch, $B1 = 2\,000$ ft-lb, and draw a parabola through the points A, B and C. (See page 79.)

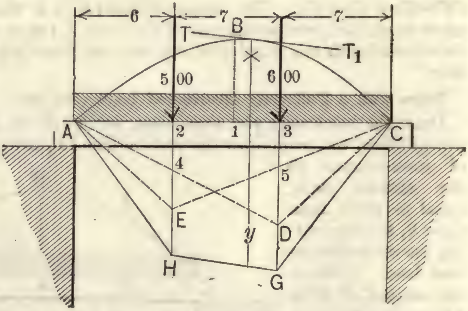

Fig. 18. Bending-moment Diagram. Distributed and Concentrated Loads

(2) The maximum bending moment for the concentrated load of 500 lb, from Case VI, is $500 \times 6 \times 14/20$, or 2 100 ft-lb. Draw $E2 = 2\,100$ ft-lb to the same scale as $B1$, and then draw the lines AE and CE.

(3) The maximum bending moment for the concentrated load of 600 lb, in like manner, is $600 \times 7 \times 13/20$, or 2 730 ft-lb. Draw $D3 = 2\,730$ ft-lb and connect D with A and C.

(4) Make EH equal to the distance from 2 to 4, and DG to the distance from 3 to 5, and draw $AHGC$.

The MAXIMUM BENDING MOMENT will be represented by the longest vertical line which can be drawn between the parabola ABC and the broken line $AHGC$. In this example the longest vertical line which can be drawn is Xy, and it scales 5 550 ft-lb.

The position of the line Xy is determined by drawing the line TT_1 parallel to HG and tangent to ABC. The vertical line Xy is drawn through the point of tangency.

Note. To change the bending moment to INCH-POUNDS multiply the moment in FOOT-POUNDS by 12.

CHAPTER X

PROPERTIES OF STRUCTURAL SHAPES. MOMENT OF INERTIA, MOMENT OF RESISTANCE, SECTION-MODULUS AND RADIUS OF GYRATION

By
CHARLES P. WARREN
ASSISTANT PROFESSOR OF ARCHITECTURE, COLUMBIA UNIVERSITY

1. The Properties of Cross-Sections

The Moment of Inertia. The strength of a cross-section to resist stresses, in either a beam or a column, depends not only upon the area but also upon the form of the cross-section. The parts of the cross-section farthest from the neutral axis, which always passes through the center of gravity of the cross-section, are much more efficient in resisting bending stresses than those parts adjacent to the axis; so that some mathematical expression must be obtained that will represent the efficiency of the entire cross-section to resist bending stresses when compared with that of any other cross-section. This expression is called the MOMENT OF INERTIA and is usually designated by the letter I.

The Moment of Inertia of any cross-section may be defined as the sum of the products obtained by multiplying each of the elementary areas of which the section is composed by the square of its normal distance from the neutral axis of the section.

By an ELEMENTARY AREA is meant an area smaller than any dealt with in simple mathematics, and it is, therefore, impossible to find an exact expression for the moment of inertia of a cross-section by such methods. By means of the calculus, however, exact formulas have been deduced from which the moments of inertia of simple geometrical forms, such as rectangles, triangles, circles, etc., may be found, with respect to different axes.

The NEUTRAL AXIS of the cross-section of a beam, girder, column, etc., which is in a state of flexure, is the line on which there is neither tension nor compression in the fibers, and when the unit stresses do not exceed the ELASTIC LIMIT of the material, it can be shown that this neutral axis passes through the CENTER OF GRAVITY of the cross-section. The normal distance of the extreme fibers from the neutral axis is usually designated by the letter c or the letter y. The former is used in the notation of this book.

Since for all sections except squares and circles, there are, in general, two neutral axes corresponding to the more common positions of the sections, it follows that there are also two moments of inertia commonly used; for a rectangle, for example, a GREATEST MOMENT OF INERTIA about an axis perpendicular to the long side and a LEAST MOMENT OF INERTIA about an axis perpendicular to the short side. The moments of inertia of the cross-sections of all rolled shapes have been calculated and are tabulated in the manufacturers' handbooks. Thus, for example, the moments of inertia of the cross-section of a 12-in, 31.5-lb **I** beam, with respect to axes perpendicular to the web and parallel to the web, are, from Table IV, equal to 215.8 and 9.5 biquadratic inches respectively. Formulas for calculating the moments of inertia of other simple sections are given on the following pages.

The Moment of Resistance. In Chapter IX, under the chapter-subdivision treating of the BENDING MOMENTS in beams, page 325, it was stated that in order to calculate the FLEXURAL STRENGTH of a beam it is necessary to ascertain the nature and extent, first, of the external forces tending to break the beam by flexure, and, secondly, of the internal forces or stresses tending to resist rupture. The external forces cause the BENDING MOMENTS,* and the internal stresses the MOMENTS OF RESISTANCE, at the various cross-sections of a beam.

The MOMENT OF RESISTANCE or the RESISTING MOMENT at any cross-section of a beam is the algebraic sum of all the moments of the internal horizontal stresses in that section with reference to a point in that section. It is usually represented by the expression SI/c, in which S is the horizontal unit stress, tensile or compressive, as the case may be, upon the fiber most remote from the neutral axis of the section, and called the FIBER-STRESS; I is the MOMENT OF INERTIA of the area of the section with reference to the NEUTRAL AXIS; and c is the shortest distance from the most remote fiber to that axis. Since, for equilibrium of forces and stresses at any cross-section of a beam, the bending moment equals the resisting moment for that section, if M represents the bending moment we have the equation

$$M = SI/c \tag{1}$$

This is known as the FLEXURE FORMULA and is universally used for investigating the flexural strength of beams.

The Section-Modulus or Section-Factor. That expression I/c in the above formula is generally known as the SECTION-MODULUS or SECTION-FACTOR. This quantity for the principal rolled sections is given in Tables IV, V, VI, VII, VIII, XI, XII, XIII and XIV. Corresponding to the two moments of inertia generally used for all sections (except for squares and circles) there are two section-moduli also, one for each axis. Thus, the section-modulus of the 12-in 31.5-lb **I** beam, with respect to a neutral axis perpendicular to the web, is $I/c = 215.8/6 = 36$; and for the axis parallel to the web, it is $I/c = 9.5/2.5 = 3.8$. For other shape the section-modulus may be found by dividing the moment of inertia by the normal distance of the extreme fiber from the neutral axis.

The Radius of Gyration. The effect of the form of the cross-section of a column on its strength is determined by a quantity called the RADIUS OF GYRATION, which is as necessary in the determination of the strength of a column as the moment of inertia is in the determination of the strength of a beam. It is denoted by the letter r. The value of the radius of gyration for any section is determined by the formula

$$r = \sqrt{I/A} \tag{2}$$

in which I is the MOMENT OF INERTIA of the section and A the SECTION-AREA. The RADIUS OF GYRATION is the normal distance from the NEUTRAL AXIS to the CENTER OF GYRATION, and the center of gyration of a section is the point where the entire area might be concentrated and have the same moment of inertia as the actual distributed area. The radius of gyration of a section is a DISTANCE and it is always less than the distance, c, from the neutral axis to the remotest fiber. For the two moments of inertia above referred to, and commonly used, there are two corresponding radii of gyration. The least of these is the one to be used in the investigation of the strength of a column as it is referred to the axis about which the column is most likely to fail. The radii of gyration of the rolled

* See Chapter IX, page 325, for definition of "bending moment."

shapes are given in the tables of the properties of sections, mentioned above. For the 12-in 31.5-lb **I** beam, $r = 4.83$ in and $r' = 1.01$ in. The radius of gyration of any other section may be found by Formula (2).

Formulas for the moments of inertia, radii of gyration and section-moduli of the principal elementary sections are given on the following pages. In the case of a hollow section or a section with a reentering hollow part, the moment of inertia of the hollow part is to be subtracted from that of the enclosing area. Moments of inertia when referred to the same axis can be added or subtracted like any other quantities which are of the same kind.

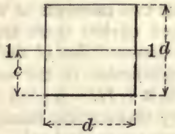
2. Areas, Moments of Inertia, Section-Moduli and Radii of Gyration of Elementary Sections

I = the moment of inertia
I/c = the section-modulus
r = the radius of gyration
A = the area of the section
c = the normal distance of most remote fiber from neutral axis

The position of axis referred to in each case is represented by the broken line 1 — 1.

SQUARE

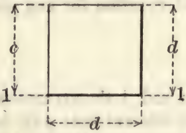
Axis of moments through center



$$A = d^2$$
$$c = \frac{d}{2}$$
$$I = \frac{d^4}{12}$$
$$\frac{I}{c} = \frac{d^3}{6}$$
$$r = \frac{d}{\sqrt{12}} = 0.288675\,d$$

SQUARE

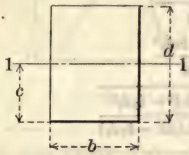
Axis of moments on base



$$A = d^2$$
$$c = d$$
$$I = \frac{d^4}{3}$$
$$\frac{I}{c} = \frac{d^3}{3}$$
$$r = \frac{d}{\sqrt{3}} = 0.577350\,d$$

RECTANGLE

Axis of moments through center



$$A = bd$$

$$c = \frac{d}{2}$$

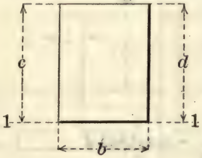
$$I = \frac{bd^3}{12}$$

$$\frac{I}{c} = \frac{bd^2}{6}$$

$$r = \frac{d}{\sqrt{12}} = 0.288675\, d$$

RECTANGLE

Axis of moments on base



$$A = bd$$

$$c = d$$

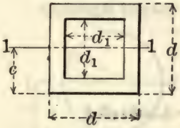
$$I = \frac{bd^3}{3}$$

$$\frac{I}{c} = \frac{bd^2}{3}$$

$$r = \frac{d}{\sqrt{3}} = 0.577350\, d$$

HOLLOW SQUARE

Axis of moments through center



$$A = d^2 - d_1^2$$

$$c = \frac{d}{2}$$

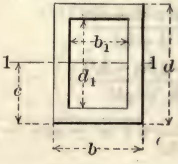
$$I = \frac{d^4 - d_1^4}{12}$$

$$\frac{I}{c} = \frac{d^4 - d_1^4}{6\,d}$$

$$r = \sqrt{\frac{d^2 + d_1^2}{12}}$$

HOLLOW RECTANGLE

Axis of moments through center



$$A = bd - b_1d_1$$

$$c = \frac{d}{2}$$

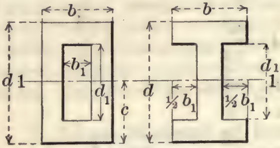
$$I = \frac{bd^3 - b_1d_1^3}{12}$$

$$\frac{I}{c} = \frac{bd^3 - b_1d_1^3}{6\,d}$$

$$r = \sqrt{\frac{bd^3 - b_1d_1^3}{12\,(bd - b_1d_1)}}$$

HOLLOW RECTANGLE AND I BEAM

Axis of moments through center



$$A = bd - b_1d_1$$

$$c = \frac{d}{2}$$

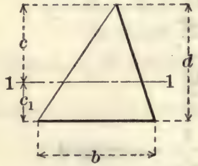
$$I = \frac{bd^3 - b_1d_1^3}{12}$$

$$\frac{I}{c} = \frac{bd^3 - b_1d_1^3}{6\,d}$$

$$r = \sqrt{\frac{bd^3 - b_1d_1^3}{12\,(bd - b_1d_1)}}$$

TRIANGLE

Axis of moments through center of gravity



$$A = \frac{bd}{2}$$

$$c = \frac{2\,d}{3} \qquad c_1 = \frac{d}{3}$$

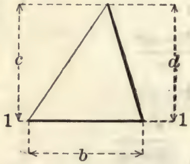
$$I = \frac{bd^3}{36}$$

$$\frac{I}{c} = \frac{bd^2}{24}$$

$$r = \frac{d}{\sqrt{18}} = 0.235702\,d$$

TRIANGLE

Axis of moments on base



$$A = \frac{bd}{2}$$

$$c = d$$

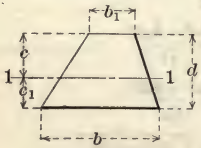
$$I = \frac{bd^3}{12}$$

$$\frac{I}{c} = \frac{bd^2}{12}$$

$$r = \frac{d}{\sqrt{6}} = 0.408248\,d$$

TRAPEZOID

Axis of moments through center of gravity



$$A = \frac{d\,(b + b_1)}{2}$$

$$c^* = \frac{d\,(b_1 + 2\,b)}{3\,(b + b_1)} \qquad {}^*c_1 = \frac{d\,(b + 2\,b_1)}{3\,(b + b_1)}$$

$$I = \frac{d^3\,(b^2 + 4\,bb_1 + b_1^2)}{36\,(b + b_1)}$$

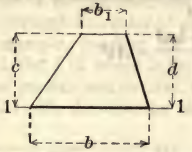
$$\frac{I}{c} = \frac{d^2\,(b^2 + 4\,bb_1 + b_1^2)}{12\,(b_1 + 2b)}$$

$$r = \frac{d}{6\,(b + b_1)}\sqrt{2\,(b^2 + 4bb_1 + b_1^2)}$$

* To find c and c_1, see Chapter VI, page 295.

TRAPEZOID

Axis of moments on base



$$A = \frac{d\,(b + b_1)}{2}$$

$$c = d$$

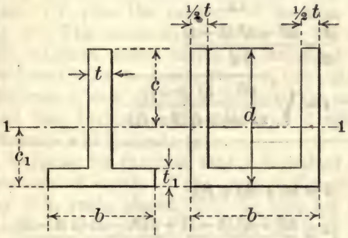
$$I = \frac{d^3\,(b + 3\,b_1)}{12}$$

$$\frac{I}{c} = \frac{d^2\,(b + 3\,b_1)}{12}$$

$$r = \frac{d}{\sqrt{6}}\sqrt{\frac{b + 3\,b_1}{b + b_1}}$$

T SECTION AND CHANNEL

Axis of moments through center of gravity



$$A = td + t_1\,(b - t)$$

$$c^* = \frac{td \times \tfrac{1}{2}\,d + t_1\,(b - t)\,(d - \tfrac{1}{2}\,t_1)}{A}$$

$$I = \frac{tc^3 + bc_1{}^3 - (b - t)\,(c_1 - t_1)^3}{3}$$

$$r = \sqrt{\frac{I}{A}}$$

CIRCLE

Axis of moments through center

$$A = \frac{\pi d^2}{4} = 0.785398\,d^2$$

$$c = \frac{d}{2}$$

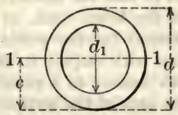
$$I = \frac{\pi d^4}{64} = 0.049087\,d^4$$

$$\frac{I}{c} = \frac{\pi d^3}{32} = 0.098175\,d^3$$

$$r = \frac{d}{4}$$

HOLLOW CIRCLE

Axis of moments through center



$$A = \frac{\pi\,(d^2 - d_1{}^2)}{4} = 0.785398\,(d^2 - d_1{}^2)$$

$$c = \frac{d}{2}$$

$$I = \frac{\pi\,(d^4 - d_1{}^4)}{64} = 0.049087\,(d^4 - d_1{}^4)$$

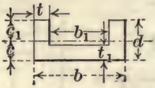
$$\frac{I}{c} = \frac{\pi\,(d^4 - d_1{}^4)}{32\,d} = 0.098175\,\frac{(d^4 - d_1{}^4)}{d}$$

$$r = \frac{\sqrt{d^2 + d_1{}^2}}{4}$$

* To find the values of c and c_1, see Chapter VI, page 295.

CHANNEL

Axis of moments through center of gravity



$$A = t_1 b + 2\,t\,(d - t_1)$$

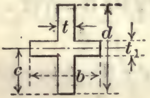
$$c^* = \frac{2\,d^2 t + d_1 t_1^2}{2\,A}$$

$$I = \frac{2\,td^3 + b_1 t_1^3}{3} - Ac^2$$

$$r = \sqrt{\frac{I}{A}}$$

CROSS-SECTION

Axis of moments through center of gravity



$$A = td + t_1\,(b - t)$$

$$c = \frac{d}{2}$$

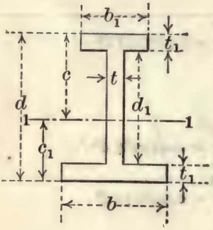
$$I = \frac{td^3 + t_1^3\,(b - t)}{12}$$

$$\frac{I}{c} = \frac{td^3 + t_1^3\,(b - t)}{6\,d}$$

$$r = \sqrt{\frac{td^3 - t_1^3\,(b - t)}{12\,(td + t_1\,(b - t))}}$$

IRREGULAR I SHAPE

Axis of moments through center of gravity



$$A = bt_1 + d_1 t + b_1 t_1$$

$$c^* = \frac{td^2 + t_1^2\,(b - t) + t\,(b_1 - t)\,(2\,d - t)}{2\,A}$$

$$I = \frac{b_1 c^3 - (b_1 - t) \times (c - t_1)^3}{3} + \frac{bc_1^3 - (b - t) \times (c_1 - t_1)^3}{3}$$

$$r = \sqrt{\frac{I}{A}}$$

* To find c and c_1, see Chapter VI, page 295.

3. Transferring Moments of Inertia to Other Parallel Axes

Explanation of Formula. It is often necessary to determine the moment of inertia with respect to some other axis than the one passing through the center of gravity of the section, such, for example, as one passing through the base and parallel to the other. Suppose it is desired to find the moment of inertia of a rectangle about an axis passing through the lower base, as in the second figure on page 335. It may be demonstrated by the principles of mechanics that the moment of inertia of any section with respect to any axis is equal to the moment of inertia of the section with respect to a parallel axis through the center of gravity, plus the product of the area of the section multiplied by the square of the normal distance between the axes. This rule may be expressed by the formula

$$I_1 = I + Ah^2 \tag{3}$$

in which I_1 is the required moment of inertia, I the moment of inertia of the section with respect to the axis through its center of gravity and parallel to the given axis, A the area of the section and h the normal distance between the axes. From this it is seen that the moment of inertia of any section-area is less for an axis through its center of gravity than for any other parallel axis.

For example, consider the rectangle shown on page 335, of breadth b and depth d, the I of which is known to be $bd^3/12$ for an axis passing through the center of gravity and parallel to the base. Then, for a parallel axis through the base, the above formula gives:

$$I_1 = \frac{bd^3}{12} + bd \times \left(\frac{d}{2}\right)^2 = \frac{bd^3}{12} + \frac{bd^3}{4} = \frac{bd^3}{3}$$

Thus the moment of inertia of the cross-section of the steel angle shown in Fig. 1, about the axis MN, is equal to the moment of inertia about the axis XX plus the product of its area multiplied by h^2. The moments of inertia for the sections of the standard rolled shapes of structural steel may be found from the tables given in this chapter. The distance c_1, also, may be found from the same tables; and this distance subtracted from d will give the distance h of Formula (3).

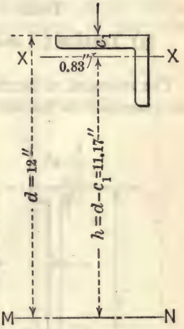


Fig. 1. Moment of Inertia of Cross-section of Steel Angle

Suppose, for example, that it is desired to find the moment of inertia of the cross-section of a 4 by 3 by ½-in angle, placed, with the long leg horizontal, about an axis MN, 12 in from the back (Fig. 1). Turning to Table XI, the area of the angle-section = 3.25 sq in. I, the moment of inertia of the angle-section about an axis 2–2, or XX of Fig. 1, parallel to the long leg = 2.4, c_1, the distance of this axis from the back of the long leg = 0.83 in and h, the distance between the axes = $(d - c_1)$ = 12 − 0.83 in = 11.17 in. Substituting these values in Formula (3)

$$I_1 = 2.4 + 3.25 \times 11.17^2 = 2.4 + 405.50 = 407.9$$

4. Moments of Inertia of Compound Sections

The Moment of Inertia of a Compound Section made up of a number of smaller sections may be found by the same formula, $I_1 = I + Ah^2$. Denote the SUM OF THE MOMENTS OF INERTIA of the separate sections making up the compound section, with respect to an axis through the center of gravity of that section, by ΣI_1. Formula (3) then becomes

$$\Sigma I_1 = \Sigma (I + Ah^2) \qquad (4)$$

That is, to find the moment of inertia of any compound section made up of a number of smaller sections:

(1) Find the moment of inertia of each of the smaller sections about an axis passing through its own center of gravity and parallel to the neutral axis of the compound section;

(2) Multiply the area of each of the smaller sections by the square of the distance between its center of gravity and the center of gravity of the whole figure;

(3) Add the results found by (1) and (2) for the moment of inertia of the whole figure.

For example, consider the cast-iron beam or lintel shown in section in Fig. 2;

(1) I of upper flange-section	$= 4 \times 1^3/12 = 4/12$
I of web-section	$= 1 \times 18^3/12 = 5\,832/12$
I of lower flange-section	$= 16 \times 1^3/12 = 16/12$
Total	$= 5\,852/12 = 487.6$
(2) Ah^2 for the upper flange	$= 4 \times (12.5)^2 = 625$
Ah^2 for the web	$= 18 \times 3^2 = 162$
Ah^2 for the lower flange	$= 16 \times (6.5)^2 = 676$
Total	$= 1\,463$

(3) Total of (1) and (2) $= 487.6 + 1\,463 = I_1$ of compound section $= 1\,950.6$

The moment of inertia of the cross-section of any compound beam, therefore, can generally be readily found by using the tables of properties of sections which

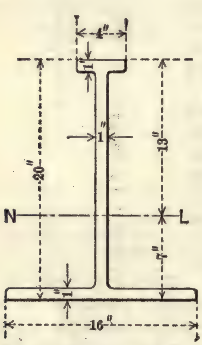

Fig. 2. Moment of Inertia of Cross-section of Cast-iron Lintel

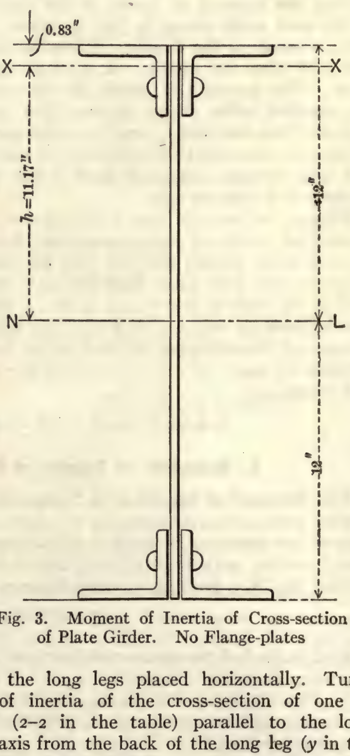

Fig. 3. Moment of Inertia of Cross-section of Plate Girder. No Flange-plates

give the numerical values of I for the various rolled shapes of which the beam is composed, with respect to the axis through the center of gravity.

The Moment of Inertia of a Single-Web Girder-Section. Consider, for example, the single-web girder shown in section in Fig. 3, and made up of one ½ by 24-in web and four 4 by 3 by ½-in flange-angles with the long legs placed horizontally. Turning to Table XI, the moment of inertia of the cross-section of one of these angles about an axis XX (2–2 in the table) parallel to the long leg = 2.4, and the distance of this axis from the back of the long leg (y in the table) = 0.83 in; hence h, the distance between the axis of the angle-section and the axis of the girder-section = 12 − 0.83 = 11.17 in. A, from the table = 3.25 sq in. The moment of inertia of the cross-section of each angle about the axis of the girder, therefore, from Formula (3), is $I_1 = 2.4 + 3.25 \times (11.17)^2 =$ 407.9, and for the four angles = 1631.6. Since the axis of the cross-section of

the web-plate is coincident with the axis of the section of the girder, its moment of inertia $= bd^3/12 = \frac{1}{2} \times (24)^3/12 = 576$. This may be found directly from Table I, page 346, Moments of Inertia of Rectangles. The moment of inertia, therefore, of the section of the compound girder $= 1631.6 + 576 = 2207.6$.

The Moment of Inertia of a Section of a Compound Girder with Flange-Plates is found in the same way, except that the moments of inertia of the sections of the flange-plates with respect to the axis of the girder-section must be added to the moments of inertia of the cross-sections of the other members. The girder in Fig. 4 is composed of one 30 by 3/8-in web-plate, four 5 by 4 by 9/16-in angles, with the longer legs horizontal, and two 12 by ½-in flange-plates.

I ($= I_1$) for cross-section of web (from Table I, page 346) $= 843.75$

I_1 for each angle-section $= I + Ah^2$ (Formula 3)

From Table XI, for each flange-angle, $I = 6.6$, $A = 4.75$ and the perpendicular distance from center of gravity to back of long leg $= 1.10$ in. Hence $h = 15 - 1.10 = 13.90$ in. $I_1 = 6.6 + 4.75 \times (13.90)^2 = 924.35$; and for four angles $= 3\,697.4$. I for the cross-section of each flange-plate $= 12 \times (\frac{1}{2})^3/12 = 0.125$, $A = \frac{1}{2} \times 12 = 6$ sq in and $h = 15 + \frac{1}{4} = 15.25$ in. For each flange-plate, then, $I_1 = 0.125 + 6 \times (15.25)^2 = 1395.125$; and for the two plates, $2\,790.25$. The moment of inertia for the cross-section of the whole girder, therefore, with reference to the horizontal axis passing through the center of gravity of the section $= 843.75 + 3\,697.4 + 2\,790.25 = 7\,331.4$.

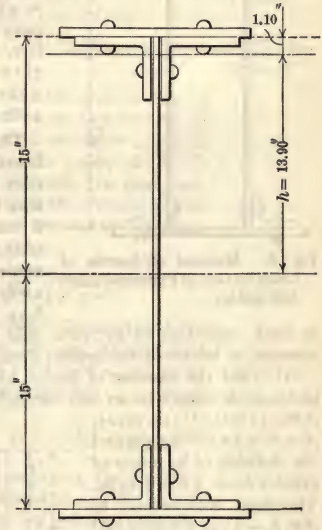

Fig. 4. Moment of Inertia of Cross-section of Plate Girder with Flange-plates

It will be noticed that the moments of inertia of the cross-sections of the flange-plates and angles about their own neutral axes is so small, compared with their moments of inertia about the neutral axis of the girder-section, that they might be omitted without any appreciable error. Therefore, in calculating the moments of inertia for riveted girders, it is the custom of many engineers to let $I_1 = Ah^2$ for flange-plate and angle-sections. In that case, for the girder-section in Fig. 4,

I for web	$= 843.75$
I_1 for angles $= Ah^2$	$= 3\,671.00$
I_1 for flange-plates $= Ah^2$	$= 2\,790.00$
Moment of inertia of entire girder-section	$= 7\,304.75$

The Moment of Inertia of a Section of a Box Girder. Let the box girder shown in Fig. 5 be composed of two 3/8 by 30-in webs, two 16 by ½-in flange-plates and four 4 by 3 by ½-in angles with the long legs horizontal.

I for each flange-plate $= bd^3/12 = 16 \times (\frac{1}{2})^3/12 = 0.16$; $A = \frac{1}{2} \times 16$ in $= 8$ sq in and $h = 15 + \frac{1}{4} = 15.25$ in. $I_1 = I + Ah^2 = 0.16 + 8 \times (15.25)^2 = 1\,860.64$; and for the two flange-plates, $3\,721.28$. I for each angle $= 2.4$, $A = 3.25$ and the distance from the back of the long leg to an axis through the center of gravity of the angle, parallel to the long leg $= 0.83$ in; so that $h = 15 - 0.83 = 14.17$ in. I_1 for the four angles is $(4 \times 2.4) + (4 \times 3.25) \times (14.17)^2 = 2\,619$. I for each web (Table I, page 346) $= 843.75$ and for the two webs $= 1\,687.5$. The moment of inertia, therefore, for the entire girder-section $= 3\,721.28 + 2\,619 + 1\,687.5 = 8\,027.78$.

Fig. 5. Moment of Inertia of Cross-section of Plate-and-angle Box Girder

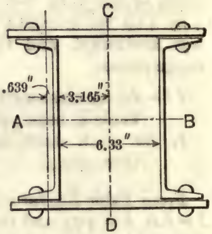

Fig. 6. Moment of Inertia of Cross-section of Plate-and-channel Box Column

The Moment of Inertia of the Section of a Channel Box Column. Fig. 6 shows the cross-section of a column made up of two 10-in 15-lb channels, set 6.33 in apart, back to back, and two ½ by 12-in side plates. Let it be required to find the moment of inertia of the section about the two axes AB and CD.

(1) Find the moment of inertia about the axis AB. I, for one of the side plates with respect to an axis through its own center of gravity and parallel to $AB = 12 \times (\frac{1}{2})^3/12 = 0.125$, $A = \frac{1}{2} \times 12$-in $= 6$ sq in and the distance of its center of gravity from AB is 5.25 in. Therefore, with respect to AB, $I_1 = 0.125 + 6 \times (5.25)^2 = 165.5$. The moment of inertia of a 10-in 15-lb channel with respect to an axis through its center of gravity and perpendicular to the web (Table VIII, page 359) $= 66.9$. Hence the moment of inertia of the whole column-section with respect to the axis $AB = (2 \times 165.5) + (2 \times 66.9) = 464.8$.

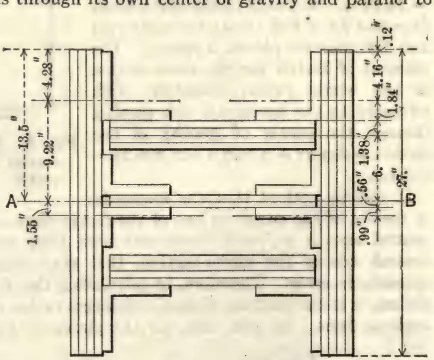

Fig. 7. Moment of Inertia of Cross-section of Three-web Plate-and-angle Box Column

(2) Find the moment of inertia about the axis CD. I, for one of the side plates (Table I, page 346) $= 72$. I, for one of the channels with respect to an axis parallel to the web $= 2.30$, $A = 4.46$ and the distance of the center of gravity from the back of the web $= 0.64$ in, approximately. Hence $h = 3.165 + 0.64 = 3.8$ in. $I_1 = 2.30 + 4.46 \times (3.8)^2 = 66.7$ and the moment of inertia of the whole column-section with respect to the axis $CD = (2 \times 72) + (2 \times 66.7) = 277.4$.

The Moment of Inertia of the Section of a Heavy Plate-and-Angle Column. Fig. 7 shows the cross-section of one of the basement-columns in the Bankers' Trust Company Building, New York City. It is made up of six flange-plates, each 27 by ¾ in section; two flange-plates, each 27 by 1 1/16 in; four flange-angles, each 6 by 6 by 15/16 in; eight outer web-plates, each 18 by 1 1/16 in; four web-angles, each 6 by 3½ by 15/16 in; and two middle web-plates each 18 by 9/16 in. What is its moment of inertia of the entire column-section with respect to the axis AB?

I for each 27 by ¾-in flange-plate (Table I) = 1 230.19	
I for six 27 by ¾-in flange-plates = 1 230.19 × 6 =	7 381.14
I for each 27 by 1 1/16-in web-plate (Table I) = 1 127.67	
I for two 27 by 1 1/16-in web-plates = 1 127.67 × 2 =	2 255.34
I for both flanges	9 636.48

For the flange-angles (Table XII, page 366) the area of a 6 by 6 by 15/16-in angle = 10.37, its I with respect to an axis parallel to AB (Fig. 7) and passing through its center of gravity = 33.7 and the distance of this axis from the back of the leg = 1.84 in. Its I_1 with respect to the axis AB is found by Formula (3), page 338, $I_1 = I + Ah^2$. $h = 13.5 - (0.12 + 4.16)$ = the distance from the axis AB to the parallel axis through the center of gravity of the angle = 9.22 in. Hence, substituting in Formula (3),

$$I_1 = 33.7 + 10.37 \times (9.22)^2 = 915.15$$

I_1 for the four flange-angles = 915.15 × 4 = 3 660.60

Each outer web is 4 × 1 1/16 in = 2¾ in thick. Hence the I for each outer web about the horizontal axis through its center of gravity = $18 \times (2.75)^3/12 = 31.2$. A = 18 by 2.75 in = 49.5 sq in. The distance from its center of gravity to the axis AB is 13.5 − (1.38 + 1.84 + 4.16 + 0.12) = 6.01 or, say 6 in.

From Formula (3), therefore, $I_1 = 31.2 + 49.5 \times 6^2 = 1\,813.2$ and for both outer webs $I_1 = 1\,813.2 \times 2 =$ 3 626.4

For the four web-angles, from Table XI, page 363, the area of a 6 by 3½ by 15/16-in angle = 8.03, its I with respect to an axis through its center of gravity and parallel to the long leg = 6.9 and the distance of this axis from the back of the long leg = 0.99 in. h, the horizontal distance between the two axes = 9/16 in, or 0.5625 in (the thickness of one of the middle web-plates) + 0.99 = 1.55 in, approximately. Therefore, for one web-angle, from Formula (3),

$$I_1 = 6.9 + 8.03 \times (1.55)^2 = 26.17$$

and for the four angles, $I_1 = 26.17 \times 4 =$ 104.68

The middle web-plates are together 9/16 in × 2 = 1⅛ in = 1.125 in thick. The I (= I_1) for the two plates is $18 \times (1.125)^3/12 =$ 2.14

The moment of inertia of the entire column-section for the axis AB is, therefore, the sum of these moments of inertia for the different parts:

I_1 for the eight flange-plates	9 636.48
I_1 for the four flange-angles	3 660.60
I_1 for the eight outer web-plates	3 626.40
I_1 for the four web-plates	104.68
I_1 for the middle web-plates	2.14
The moment of inertia for the entire section	17 030.30

5. Radii of Gyration of Compound Sections

The Radius of Gyration of any Compound Section may be found from Formula (2), page 333, by dividing the moment of inertia of the section by the total area of the section and taking the square root of the quotient. Thus, the radii of gyration of the channel-column section shown in Fig. 6, about the axes AB and CD, are found as follows: A = (the sum of the areas of two ½ by 12-in plates, or 12 sq in) + (the sum of the areas of the two channels, or 8.92 sq in) = 20.92 sq in. I about $AB = 464.8$ and about $CD = 277.4$.

Therefore, r, with respect to the axis $AB = \sqrt{\dfrac{464.8}{20.92}} = 4.71$

and r_1, with respect to the axis $CD = \sqrt{\dfrac{277.4}{20.92}} = 3.68$

Since r_1 is the smaller, it is the value to be used in the column-formula. It is to be noted that this value of r agrees with the r of the 10-in channel-column in Table XXV, on page 533. The value of r_1 does not, however, agree exactly with the r_1 in the same table, the variation being caused by a difference in the spacing of the channels, back to back.

The Least Radius of Gyration of a Section of a Plate-and-Angle Column. As another example, let it be required to find the least radius of gyration of the cross-section of the plate-and-angle column shown in Fig. 8, made up of one ⅜ by 12-in web-plate, two ⅜ by 12-in side plates and four 4 by 4 by ½-in angles.

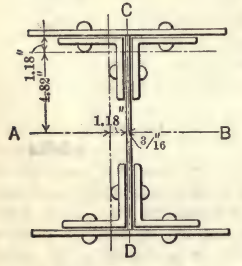

Fig. 8. Least Radius of Gyration of Cross-section of Plate-and-angle Column

(1) Find the moment of inertia about the axis AB. For the axis AB, I for each one of the side plates with respect to an axis through its own center of gravity and parallel to the axis $AB = 12 \times (3/8)^3/12 = 0.05$. $A = 3/8 \times 12 = 4.5$ sq in and $h = 6\frac{3}{16}$ in. $I_1 = 0.05 + 4.5 \times (6\frac{3}{16})^2 = 172.33$. I for each one of the angles with respect to an axis through its center of gravity and parallel with the flange-leg is 5.6, $A = 3.75$ and the distance of the center of gravity from the back of the flange of the angle = 1.18. Hence, $h = 6$ in $- 1.18$ in $= 4.82$ in and I_1 for each angle $= 5.6 + 3.75 \times (4.82)^2 = 92.71$. I for the web-plate = 54. The moment of inertia of the whole column-section, therefore, about the axis $AB = (2 \times 172.33) + (4 \times 92.71) + 54 = 769.50$.

(2) Find the moment of inertia about the axis CD. I for each side plate = 54. I for each angle = 5.6 and A for each angle = 3.75. The distance of the center of gravity of each angle from the back of the flange of the angle = 1.18 in and hence, $h = 1.18$ in + $\frac{3}{16}$ in = 1.36 in, approximately. I_1 for each angle $= 5.6 + 3.75 \times (1.36)^2 = 12.54$. I for each web-plate = 0.05. The moment of inertia of the whole column-section, therefore, about the axis $CD = (2 \times 54) + (4 \times 12.54) + 0.05 = 158.21$.

Since this is the least moment of inertia the least radius of gyration will likewise be about the axis CD. The area of the cross-section of the column = (4×3.75, the area of the angles) + (3×4.5, the area of each plate) = 28.5. $r^2 = 158.21/28.5 = 5.55$ and r, the least radius of gyration = 2.35.

The Radius of Gyration of the Cross-Section of a Hollow Rectangular Column. As another example, let it be required to find the radius of gyration of the cross-section of a hollow rectangular cast-iron column with outside dimensions 6 by 6 in and with a shell ¼ in thick. (See figures and formulas for hollow squares and rectangles, page 335.) $A = 6^2 - (5.5)^2 = 36 - 30.25 = 5.75$ sq in. $I = (bd^3 - b_1b_1^3)/12 = [6^4 - (5.5)^4]/12 = (1\ 296 - 910)/12 = 386/12 = 32.2$. $r^2 = 32.2/5.75 = 5.6$ and $r = 2.37$ in.

The radii of gyration of round-section columns and square-section columns, varying from 2 to 20 in in diameter and of metal varying from ¼ to 2 in thick, are given in Tables II and III, see pages 348 to 351. For example: the radius of gyration of a 6 by 6-in square-section cast-iron column with a shell ¼ in thick, is, from Table III, 2.35 in.

Table I.* Moments of Inertia of Rectangles

Neutral axis through center and normal to depth

Depth in inches	Widths of rectangles in inches						
	1/4	5/16	3/8	7/16	1/2	9/16	5/8
2	0.17	0.21	0.25	0.29	0.33	0.38	0.42
3	0.56	0.70	0.84	0.98	1.13	1.27	1.41

6. Dimensions, Moments of Inertia, Radii of Gyration and Section-Moduli of Standard Structural Shapes

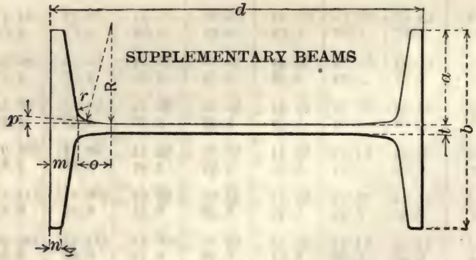
Explanation of Tables. As in using structural-steel shapes the choice is practically confined to such shapes as are rolled by the mills, it is essential to have at hand the dimensions and properties of those shapes in order to calculate the necessary sizes to meet special requirements for strength and practical conditions of economy and framing. Since 1890 great changes have been made both in the materials and in the shapes of the standard sections. The rolling-mills which manufacture the most complete assortment of structural shapes are those of the Carnegie Steel Company, the Cambria Steel Company, the Jones & Laughlin Steel Company and the Bethlehem Steel Company. In general, the products of these mills, especially beams and channels, are respectively similar in shape. This is particularly true of the shapes rolled by the first three of the companies named.

The standard steel beams and channels considered in the following pages are rolled by all of these mills, with the exception of those of the Bethlehem Steel Company. With a few exceptions the following tables of properties of standard structural shapes are adapted from the 1915 edition of the Pocket Companion of the Carnegie Steel Company. It may be well to state that the tables of properties for the various structural shapes, published by the companies named above, do not agree exactly, even for the same weights, but the differences are not of practical importance. The tables of the Cambria Steel Company and of the Carnegie Steel Company for beams and channels agree more closely. As angles are very extensively used for a great many purposes, the properties are given for all sizes rolled and also a table showing from which mills the different sizes may be obtained. Naturally it will generally be advantageous to use a size that is rolled by several mills.

Tables XV, XVI and XVII will be found very convenient when computing the strength of struts formed of pairs of angles, and Table XVIII when computing the same for pairs of channels.

Standard Steel Beams and Channels*

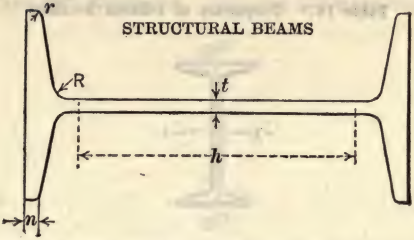
Common Dimensions



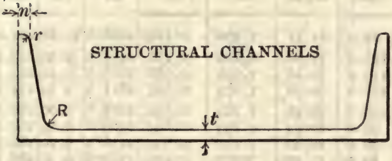
$b = d/6 + 3$	$o = 3.82\,t - 0.10$
$t = 0.01125\,d + 0.12$	p, computed
$n = 0.01875\,d + 0.09$	$r = 1.48\,t + 0.02$
$m = n + (b - t)/12$	$R = 16.78\,t - 0.66$

Slope of flange, $1 : 6 = 16\frac{2}{3}\% = 9° \, 27' \, 42''$

* From Pocket Companion, 1915 Edition, Carnegie Steel Company, Pittsburgh, Pa.



n = minimum web = t
R = minimum web + 0.10
r = $\frac{9}{10}$ minimum web
h = distance between flange-fillets
Slope of flange, 1 : 6 = 16⅔% = 9° 27′ 42″



n = minimum web = t
R = minimum web + 0.10
r = $\frac{9}{10}$ minimum web
Slope of flange, 1 : 6 = 16⅔% = 9° 27′ 42″

All dimensions are in inches and apply only to the minimum-weight beams or channels.

Dimensions given for structural beams are those adopted in 1896, by the Association of American Steel Manufacturers and apply to all beam-sections shown on the pages of the Carnegie Steel Company's Pocket Companion, 1915 Edition, except the American Standard beam-sections B 1, B 2 and B 3, beam-sections B 24 and B 81, and supplementary beams B 31 to B 38, inclusive.

Dimensions shown for structural channels are those adopted by the Association of American Steel Manufacturers and apply to all structural channel-sections.

* Rolled by the Jones & Laughlin Steel Company, Pittsburgh, Pa.

Table X. Sizes and Makes of Rolled Steel Angles

The following table has been compiled to show angles of various sizes rolled by different companies. The word "all" indicates that angles of the sizes mentioned are rolled by all the companies included in the list. The abbreviations refer to the following companies: Cam., Cambria Steel Company; Car., Carnegie Steel Company; J. & L., Jones & Laughlin Steel Company.

Angles with unequal legs		Angles with equal legs	
Sizes in inches	Companies	Sizes in inches	Companies
8 ×6	Cam. and Car.	8 ×8	All
8 ×3½	Car.	6 ×6	All
7 ×3½	All	5 ×5	All
6 ×4	All	4½×4½	Cam.
6 ×3½	All	4 ×4	All
5 ×4	All	3½×3½	All
5 ×3½	All	3¼×3¼	J. & L.
5 ×3	All	3 ×3	All
4½×3	Car. and J. & L.	2¾×2¾	Cam. and J. & L.
4 ×3½	All	2½×2½	All
4 ×3	All	2¼×2¼	Cam. and J. & L.
3½×3	All	2 ×2	All
3½×2½	All	1¾×1¾	All
3¼×2	J. & L.	1½×1½	All
3¼×1½	J. & L.	1⅜×1⅜	J. & L.
3 ×2½	All	1¼×1¼	All
3 ×2	All	1³⁄₁₆×1³⁄₁₆	J. & L.
2½×2	All	1 ×1	All
2½×1¾	J. & L.	¾× ¾	J. & L.

This table and the two following are employed in computing the safe resistance to compressive stress of two angles, back to back, used as struts or as the compression-chords of roof-trusses, etc., by the following rule:

Obtain from the compression-formula in use the allowed stress per square inch corresponding to the ratio of slenderness of the section, and multiply that value by the area. The result will be the allowable compressive stress.

Example 1. Section given. Required the safe load in compression, as per formula $S = 19\,000 - 100\,l/r$, on a strut composed of two angles, 4 by 4 by ¼ in, back to back, with an unsupported length of 9 ft.

Area of section, $A = 3.88$ sq in; least radius of gyration, $r = 1.25$ in.

Ratio of slenderness, $l/r = 9 \times 12 \div 1.25 = 86.4$.

Allowed unit stress, $S = 19\,000 - 100 \times 86.4 = 10\,360$ lb per sq in.

Safe load, $AS = 3.88 \times 10\,360 = 40\,200$ lb.

Example 2. Stress given. Required a section for a member in compression, 12 ft 3 in long, made of two angles separated by ½-in gusset-plates, to resist a total stress of 35 000 lb; ratio of slenderness not to exceed 120.

Assume two angles, 5 by 3 by 5/16 in, long legs back to back.

Area of section, $A = 4.80$ sq in; least radius of gyration, $r = 1.26$ in.

Ratio of slenderness, $l/r = 12.25 \times 12 \div 1.26 = 116.7$.

Allowed unit stress, $S = 19\,000 - 100 \times 116.7 = 7\,330$ lb per sq in.

Safe load, $AS = 4.80 \times 7\,330 = 35\,200$ lb.

In the first case the least radius of gyration is that about the axis 1-1; in the second case, about the axis 2-2; in all cases the least radius of gyration determines the ratio of slenderness and therewith the allowed safe compressive stress. In all cases, also, the two angles are to be secured together by stay-rivets, so spaced as to insure that the section acts as a unit. The ratio of slenderness of any single angle between rivets must always be less than that of the strut or compression-chord.

CHAPTER XI

RESISTANCE TO TENSION. PROPERTIES OF IRON AND STEEL

By

HERMAN CLAUDE BERRY

PROFESSOR OF MATERIALS OF CONSTRUCTION, UNIVERSITY OF PENNSYLVANIA

1. Definitions, Working Stresses and Examples

The Ultimate Tensile Strength of a material is the amount of internal stress which a section one square inch in area is capable of exerting against an external axial force. It is the UNIT STRESS OR INTENSITY OF STRESS, expressed in pounds per square inch, which the material can withstand. It is often called the ULTIMATE STRENGTH OR ULTIMATE STRESS of the material. Its value for any material depends on the tenacity of the fibers or the cohesion of the particles of which the material is composed.

An Axial Force is one which acts uniformly over the section of a prismatic body so that the resultant of the distributed forces coincides with the axis of the body. Hence the total AXIAL FORCE which any cross-section of a body will resist is the product of the ultimate strength of the material and the area of the cross-section, in square inches.

Safe Working Stress. The ultimate strength of different building materials has been found by pulling apart bars of known dimensions and dividing the maximum load each sustained by the area of the bar before testing. This ultimate strength, however, must not be used to proportion the size of members of structures, because of variations in material, hidden defects and imperfect workmanship; and, especially, because of indefiniteness as to the maximum load that may be imposed on the structure. To provide safety against the rupture of a member and the consequent failure of the structure from any of these causes, the proportions of the members must be based on SAFE WORKING STRESSES which are usually some fractional part of the ultimate strength found by experiment to provide proper security against failure.

The Factor of Safety is the ratio of the ultimate strength to this safe working stress for that material. Its value ranges generally from 2 to 10, depending upon the nature of the material and the service to which it is applied.

Safe Working Stress in Tension. Table I gives these values for various building materials. The total SAFE LOAD that may be applied to a piece of material of uniform section is found by multiplying the cross-section of the piece, in square inches, by the safe working stress opposite the name of the material of which the piece is composed.

Then if P = the safe load in lb,

S_t = the allowable safe working stress in tension,

b = the width of a rectangular bar,

h = the depth of a rectangular bar,

d = the diameter of a round bar,

there results, for a rectangular bar,

$$P = bhS_t \tag{1}$$

and for a round bar,

$$P = 0.7854\, d^2 S_t \tag{2}$$

The area of cross-section to support a load P is, for a rectangular bar,

$$A = \frac{P}{S_t} \tag{3}$$

and for a round bar

$$d = \sqrt{\frac{P}{0.7854\, S_t}} \tag{4}$$

Table I. Safe Working Stress in Tension for Building Materials

Material	Safe stress lb per sq in (S_t)
Cast iron	3 000
Wrought iron	12 000
Steel, medium	16 000
Chestnut	850
Douglas fir	800
Hemlock	600
Pine, long-leaf yellow	1 200
Pine, short-leaf yellow	900
Pine, Norway	800
Pine, white	700
Redwood	700
Spruce	800
White oak	1 200

Example 1. What size of medium-steel angle should be used to sustain a tensile force of 64 000 lb?

Answer. By formula (3),

$$\text{the net sectional area} = \frac{64\,000}{16\,000} = 4.00 \text{ sq in}$$

From the Table of the Properties of Angles (Chapter X) we find that a 4 by 4 by ⅝-in angle has an area of 4.61 sq in, which is to be reduced by a ⅞-in hole for a ¾-in rivet, leaving $4.61 - (7/8 \times 5/8) = 4.06$ sq in, net area. This is slightly in excess of the required amount.

The SAFE LOAD for angles commonly used in roof-trusses is given in Table X; and the REDUCTION IN SECTIONAL AREA caused by rivet-holes, in Table XI, this chapter, and in Table I, Chapter XX. See, also, Chapter XII, page 414, paragraph on Punching Rivet-Holes.

Example 2. What size of white-pine tie-beam should be used to sustain a tensile force of 60 000 lb?

Answer. By formula (3),

$$\text{the net sectional area} = \frac{60\,000}{700} = 85.7 \text{ sq in}$$

If the depth is taken at 12 in, the net width must be $\frac{85.7}{12} = 7.2$ in. Allowance must be made for the increase in tension on the lower side of the beam, due to its own weight, and also for any cutting that may be necessary in making the connections or holes for truss-rods. If there is a 2-in hole through the beam, a

10 by 12-in timber must be used. This makes allowance for the weight of the beam itself. If the unsupported length of the beam is great, the allowance for the weight must be made according to the methods explained in Chapter XV, page 572, for the calculation of tie-beams subjected to transverse loading.

2. Wrought Iron

Manufacture. Wrought iron is a mixture of pure iron and slag, about 96% iron and 3% slag, together with from ½ to ¾% of other elements including carbon, phosphorus, sulphur and manganese. It is made from pig iron and iron oxide, or mill-scale, in a reverberatory furnace consisting of a firebox, a hearth or working-chamber, and the necessary dampers and flues. The impurities are removed from the iron at different stages in the process, silicon and manganese during the melting-down stage, part of the phosphorus and sulphur during the clearing-stage and the carbon and remainder of the phosphorus and sulphur during the boiling-stage. The iron is then in a pasty condition ready for a thorough stirring by the workman, who collects it into balls of about 80 lb weight and takes it to a squeezer or forge where the greater part of the slag is removed. It is then rolled out into MUCK-BARS. These bars are cut into pieces which are piled into bundles suited to the size of the finished bar. The piles are heated and rolled again. The rolling reduces the amount of slag and makes the material denser. The process of rerolling may be repeated a number of times to produce double or triple-refined MERCHANT-BAR IRON.

The Appearance of Wrought Iron is very much like that of steel. It may be distinguished from steel by nicking one side of the bar and bending it away from the nick. Iron will split along the slag-laminations and show the COARSELY FIBROUS nature of the material; while steel will bend or rupture at the nick without splitting, any fracture being FINELY FIBROUS or CRYSTALLINE. When ruptured in a tension-test wrought iron shows a dark fibrous fracture. If the specimen is grooved before testing or broken in impact the fracture will be coarsely crystalline.

Welds. Wrought iron is more easily welded than steel because the work may be accomplished through a wider range of temperature than with steel. A weld may develop the full strength of the bar, but tests on hand-forged welds on rough tie-bars reported by Kirkaldy gave average values of about 60% of the strength of the bar.

Use. Wrought iron is no longer used for the manufacture of structural shapes, such as angles, channels and beams, its use for structural work being practically limited to bars, rods and bolts. It can be worked more easily than steel in threading-machines; and on this account, unless steel is specified, some companies will furnish truss-rods, bolts, etc., in wrought iron.

Specifications* for Wrought Iron. Wrought iron may be purchased under the Specifications of the American Society for Testing Materials. The more important paragraphs† for the grades of MERCHANT IRON are:

Process of Manufacture. 1. Wrought iron shall be made by the puddling or the charcoal-hearth process or rolled from fagots or piles made from wrought-iron scrap, alone or with muck-bar added.

Physical Properties. TENSION-TEST. 2. The minimum physical qualities required in the four classes of wrought iron shall be as follows:

* For amendments the Year Books of this society should be consulted.
† Some of the numbered paragraphs are purposely omitted.

Properties considered	Stay-bolt iron	Merchant iron		
		Grade A	Grade B	Grade C
Tensile strength, lb per sq in...	46 000	50 000	48 000	48 000
Yield-point, lb per sq in.......	25 000	25 000	25 000	25 000
Elongation, percentage in 8 in...	28	25	20	20

4. Nicking-Test. When the specimen is slightly and evenly nicked on one side and bent back through an angle of 180° it shall show the following fractures:

(b) Merchant iron, Grade A, a long, clean, silky fiber, free from slag or dirt or any coarse crystalline spots. A few fine crystalline spots may be tolerated, provided they do not in the aggregate exceed 10% of the sectional area of the bar.

(c) Merchant iron, Grade B, a generally fibrous fracture, free from coarse crystalline spots. Not over 10% of the fractured surface shall be granular.

(d) Merchant iron, Grade C, a generally fibrous fracture, free from coarse crystalline spots. Not over 15% of the fractured surface shall be granular.

5. Cold Bending-Test. A specimen cut from the bar as rolled shall be bent through an angle of 180° by pressure or by a succession of light blows. The classes of Merchant iron shall conform to the following bending-tests:

(f) Merchant iron, Grade A, shall bend, cold, 180° flat on itself, without fracture on the outside of the bent portion.

(g) Merchant iron, Grade B, shall bend, cold, 180° around a diameter equal to the thickness of the specimen tested, without fracture on the outside of the bent portion.

(h) Merchant iron, Grade C, shall bend, cold, around a diameter equal to twice the thickness of the specimen tested, without fracture on the outside of the bent portion.

6. Hot Bending-Test. Specimens cut from the bar as rolled, heated to a bright-red heat, shall be bent through an angle of 180° by pressure or by a succession of light blows, without hammering directly on the bend. The classes of Merchant iron shall conform to the following hot-bending tests:

(j) Merchant iron, Grade A, shall bend flat on itself, without showing cracks or flaws. A similar specimen heated to a yellow heat and suddenly quenched in water the temperature of which is between 80° and 90° F., shall bend, without hammering on the bend, 180° flat on itself, without showing cracks or flaws. A similar specimen heated to a bright-red heat, shall be split at the end and each part bent back through an angle of 180°. It shall also be quenched and expanded by drifts until a round hole is formed whose diameter is not less than nine-tenths the diameter of the rod or width of the bar. Any extension of the original split or indication of fracture, cracks, or flaws developed by the above tests will be sufficient cause for the rejection of the lot represented by that rod or bar.

(k) Merchant iron, Grade B, shall bend through 180° flat on itself, without showing cracks or flaws.

(l) Merchant iron, Grade C, shall bend sharply to a right angle, without showing cracks or flaws.

Test-Pieces and Methods of Testing. 8. Tensile Specimens. Whenever possible iron shall be tested in full-size as rolled, to determine the physical qualities specified in paragraph No. 2, the elongation being measured on an

8-in gauged length. In flats and shapes too large to test as rolled, the standard specimen shall be 1½ in wide and 8 in, gauged length.

12. THE YIELD-POINT specified in paragraph No. 2 shall be determined by the careful observation of the drop of the beam of the testing-machine.

Finish. 13. All wrought iron must be practically straight, smooth, free from cinder-spots or injurious flaws, buckles, blisters, or cracks. In round iron, sizes must conform to the Standard Limit gauge as adopted by the Master Car Builders' Association in November, 1883.

3. Cast Iron

Cast Iron has been defined as a saturated solution of carbon in iron, the carbon-content varying from 1½ to 4% according to the other impurities contained. It is hard, brittle, non-malleable and very fluid when melted, so that it is well adapted for casting into complex forms.

Manufacture. It is produced in the blast-furnace, which is essentially a closed refractory-lined stack, with a valve-charging device at the top, tuyeres or openings in the lower part for the introduction of the air-blast, and a hearth at the bottom with a tap-hole for the periodic withdrawal of the iron and slag. The FURNACE-IRON is cast into PIGS about 3 ft long and weighing about 100 lb each. FOUNDRY-CASTINGS are made from PIG IRON and SCRAP melted in a cupola and poured into green-sand molds. The charge is made up of different quantities of the different grades of pig so as to control the physical properties of the castings, principally through control of the silicon-content.

Appearance. CASTINGS have a gray or white fracture according to the condition of the contained carbon, the gray fracture indicating graphitic or separated carbon and the white the combined carbon. GRAY IRON is softer and tougher and is specified for ordinary CASTINGS.

Strength. Cast iron does not have a definite ELASTIC LIMIT. A relatively small stress will produce some permanent deformation. Its ULTIMATE TENSILE STRENGTH varies from 15 000 to 20 000 lb per sq in; and in some iron is as high as 30 000 lb per sq in. Its COMPRESSIVE STRENGTH varies over a wide range, 80 000 lb per sq in being a fair average value.

Defects. Castings are liable to several common DEFECTS the chief of which are blow-holes due to the formation of steam from the damp molds, sand-holes due to misplaced sand, rough surfaces, cold shuts due to chilling of the iron and failure to fill the parts of the mold, shrinkage-cracks due to uneven cooling of the castings in parts of different thickness. In cored castings, also, the walls are frequently of variable thickness because of the shifting of the cores. This is especially frequent in case of hollow columns cast in a horizontal position. Because of these defects and on account of the low ULTIMATE STRENGTH, cast iron should never be used where it is subjected to any great tensile stress.

Specifications* for Cast Iron. The specifications of the American Society for Testing Materials, for GRAY-IRON CASTINGS, include the following paragraphs:

1. Unless FURNACE-IRON is specified, all GRAY CASTINGS are understood to be made by the CUPOLA-PROCESS.

2. The SULPHUR-CONTENTS are to be:

For light castings, not over 0.08 per cent.
For medium castings, not over 0.10 per cent.
For heavy castings, not over 0.12 per cent.

3. In dividing castings into LIGHT, MEDIUM and HEAVY classes, the following standards have been adopted:

* For amendments the Year Books of this society should be consulted.

Castings having any section less than ½ in thick shall be known as LIGHT CASTINGS.

Castings in which no section is less than 2 inches thick shall be known as HEAVY CASTINGS.

MEDIUM CASTINGS are those not included in the above classification.

4. TRANSVERSE TEST. The minimum BREAKING STRENGTH of the ARBITRATION-BAR under transverse load shall be:

For light castings, not under 2 500 lb.
For medium castings, not under 2 900 lb.
For heavy castings, not under 3 300 lb.

In no case shall the DEFLECTION be under 0.10 in.

TENSION-TEST. Where specified this shall be:

For light castings, not less than 18 000 lb per sq in.
For medium castings, not less than 21 000 lb per sq in.
For heavy castings, not less than 24 000 lb per sq in.

The specifications give explicit directions for casting the ARBITRATION-BAR, which is 1¼ in in diameter and 15 in long. Two of these are cast for each twenty tons of castings. One of each pair must fulfill the requirements to permit acceptance of the castings. The bar is loaded at the middle at a rate that will cause a 0.10-in deflection in from twenty to forty seconds. The tension-test is not recommended.

11. CASTINGS shall be true to pattern, free from cracks, flaws and excessive shrinkage. In other respects they shall conform to whatever points shall be specially agreed upon.

4. Steel

Steel is a mixture of compounds of iron and carbon with small quantities of other elements, including manganese, phosphorus, sulphur, silicon, etc. The carbon-content controls the hardness and strength of the steel. Less than 0.10% of carbon is present in the soft steels, which have most of the characteristics of wrought iron; while steel with more than 0.40% carbon is capable of being tempered, cannot be welded and is very much stronger. Manganese acts as a cleanser during the process of manufacture, and increases the forgeability of the steel. Phosphorus and sulphur are harmful in their effects, phosphorus making steel brittle under sudden loading and sulphur making it hot-short or brittle when heated.

Manufacture. STRUCTURAL STEEL is manufactured by the BESSEMER and the OPEN-HEARTH PROCESSES. In the first, molten cast iron is charged into a Bessemer converter, an air-blast is driven through the charge from perforations in the false bottom of the converter and the silicon, sulphur and carbon burned out. Carbon in the form of ferro-manganese is then added to deoxidize the charge and give the proper content of carbon in the finished steel, which is quickly drawn off and poured into ingots. Phosphorus is not removed ordinarily by the Bessemer process; but if the lining of the converter is made of basic material, such as dolomite limestone, and if lime is added with the charge, the phosphorus will unite with it and be poured off with the slag.

The Open-Hearth Process. In this process scrap-steel, pig-iron or molten furnace-iron and limestone flux are charged on the hearth of a Siemens furnace, a reducing gas-flame is directed onto the charge and the carbon and other impurities are gradually removed. When the reduction is about completed samples are taken and carbon determined so that the charge may be withdrawn at the proper time. The process thus permits of much more accurate control of

the product. The material is more uniform and consequently more dependable in service than BESSEMER STEEL. OPEN-HEARTH STEEL is used for most structural work.

Phosphorus may be removed by the basic process as in case of Bessemer steel. Ores running low in phosphorus are generally used in America so that the basic process is little employed here.

The Effect of Carbon and Phosphorus on the STATIC STRENGTH of steel for the limits of carbon included in structural steel is an increase in strength of about 1 000 lb per sq in for each 0.01% increase in either element. Cunningham's formula

$$S_t = 40\,000 + 100\,000\,(C + P)$$

gives the approximate relation between the strength and the chemical composition. C and P are respectively the amounts of carbon and phosphorus expressed in percentage. For example, the ULTIMATE STRENGTH of a steel having 0.15% carbon and 0.07% phosphorus is, approximately,

$$S_t = 40\,000 + 100\,000\,(0.15 + 0.07) = 62\,000 \text{ lb per sq in}$$

The Percentage of Elongation decreases as the carbon-content and ULTIMATE STRENGTH increase. An approximate relation being

$$\text{percentage of elongation} = \frac{1\,400\,000}{S_t}$$

Since the TOTAL ELONGATION of a ruptured specimen is due to the local stretching at the point of rupture and the uniform elongation over the whole gauge-length, it is necessary to report the gauge-length when reporting this result. Since the LOCAL ELONGATION is the same for a 2 or an 8-in length, the PERCENTAGE OF ELONGATION for the same material, tested on a 2-in gauge-length, is greater than if measured on an 8-in length.

The Elastic Behavior of a specimen of steel loaded to rupture is best shown by a STRESS-STRAIN DIAGRAM on which the stresses are plotted as vertical ordinates and the elongations or strains as abscissas, as in Fig. 1. Five significant results are shown:

(1) **The Modulus of Elasticity** (E). The relation between the stress and the strain or elongation is called the MODULUS OF ELASTICITY. It is equal to the unit stress divided by the unit strain or deformation and is represented graphically by the tangent of the angle of the initial line with the horizontal. Its value for steel for tension is about 30 000 000 lb per sq in.

(2) **The Elastic Limit** ($E.L.$) is that unit stress beyond which the ratio of stress to strain ceases to be constant, or beyond which the curve ceases to be a straight line.

(3) **The Yield-Point** ($Y.P.$), slightly above or beyond the ELASTIC LIMIT, is that unit stress at which the specimen begins to stretch without increase in the load. This stress may be determined from a test without the use of delicate measuring-apparatus by the DROP OF THE BEAM or HALT IN THE GAUGE of the testing-machine.

(4) **The Ultimate Strength** ($U.S.$) is the greatest unit stress the specimen can sustain.

(5) **The Rupture-Stress** (R) is the unit stress at the time of failure. This is the unit stress at the point of failure after the area of the cross-section of the specimen has been reduced; and because of the rapid dropping off of the load it is difficult to determine. It is not regularly observed in testing, attention

being called to it merely to emphasize the fact that the ULTIMATE STRENGTH of steel is not the stress at the time of failure of the specimen. This is true, also, for wrought iron and ductile materials in general.

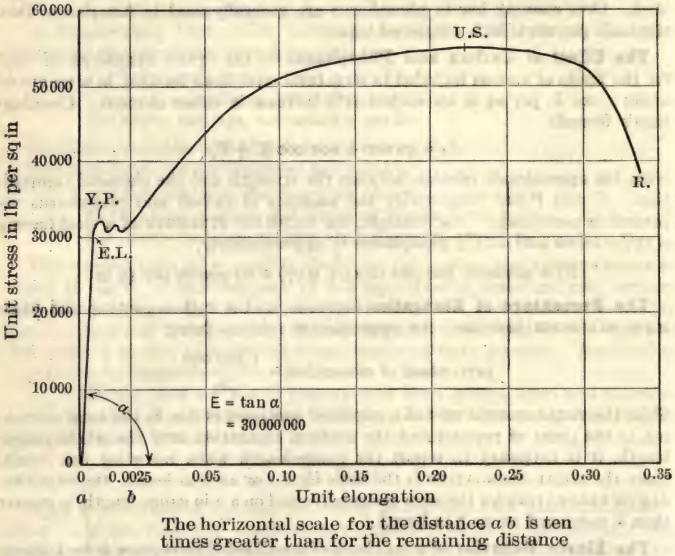

Fig. 1. Stress-strain Diagram of Test on Steel Specimens.

Effect of Punching and Shearing. Structural steel is hardened by the action of the punch and shear in the process of manufacture in the shop. On the die-side the metal is forced to flow from the tool and this cold working hardens and injures it as may be shown by a cold-bend test. The effect may be removed by annealing; but in the best work it is usually specified that rivet-holes shall be reamed during the assembling of the parts. This removes the injured metal and brings the parts into better alinement for the insertion of the rivets. The injury from shearing may be removed by milling the sheared edges.

The Coefficient of Expansion of steel is 0.000 006 5 per degree Fahrenheit. The ELONGATION in a length l, due to a change in temperature of t degrees, is then

$$e = 0.000\,006\,5\,lt$$

in which l is expressed in inches and t in degrees Fahrenheit.

The Weight of Steel is taken at 489.6 lb per cu ft. The sectional area of a member in square inches multiplied by 3.4 equals the weight in pounds per linear foot.

The Working Stress for structural steel in tension in buildings and bridges is 16 000 lb per sq in in most specifications and building laws. For members subject to constant load some designers use a WORKING STRESS of 20 000 lb per sq in.

5. Standard Specifications * for Structural Steel for Buildings

Specifications. Structural steel may bepu rchased under the specifications of the Association of American Steel Manufacturers or of the American Society for Testing Materials. Extracts from these specifications follow:

Manufacture. (1) Structural steel may be made by either the open-hearth or Bessemer process.

Rivet-steel and plate or angle-material over ¾ in thick, which is to be punched, shall be made by the open-hearth process.

Chemical and Physical Properties. (2) They shall conform to these limits:

Properties considered	Structural steel	Rivet steel, open hearth
Phosphorus, maximum, Bessemer	0.10 per cent	....
Phosphorus, maximum, open-hearth	0.06 per cent	0.06 per cent
Sulphur, maximum	....	0.045 per cent
Ultimate tensile strength, lb per sq in	55 000–65 000	46 000–56 000
Yield-point	½ ult. tens. str.	½ ult. tens. str.
Elongation, min per cent in 8 in (Fig. 2)	$\frac{1\ 400\ 000^*}{\text{Ult. tens. str.}}$	$\frac{1\ 400\ 000}{\text{Ult. tens. str.}}$
Cold bend without fracture	180° to diameter of 1 thickness	180° flat

* See Percentage of Elongation, page 384.

For the purposes of these specifications, the yield-point shall be determined by the careful observation of the drop of the beam of the testing-machine.

Chemical Determinations. (3) In order to determine if the material conforms to the chemical limitations prescribed in paragraph (2) herein, analysis shall be made by the manufacturer from a test-ingot taken at the time of the pouring of each melt or blow of steel, and a correct copy of such analysis shall be furnished to the engineer or his inspector.

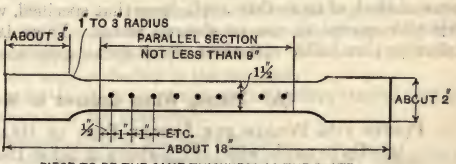

Fig. 2. Form of Specimen for Steel-test

Form of Specimens. (4) Specimens for tension-tests and bending-tests shall be made by cutting from the finished product coupons, which shall have both faces rolled and both edges milled to the form shown in Fig. 2; or both edges parallel; or they may be turned to a diameter of ¾ in for a length of at least 9 in and have enlarged ends.

(a) For material more than ¾ in thick the bending-test specimen may be 1 in by ½ in in section.

(b) Rivet-rounds and small rolled bars shall be tested as rolled.

* Revisions of form or substance of matter of some paragraphs, as (3), (4), (5), (7) and (11), have been proposed or adopted (1914-15). For amendments see Year Books of the Am. Soc. for Test. Mats.

Annealed Specimens. (5) Material which is to be used without annealing or further treatment shall be tested in the condition in which it comes from the rolls. When material is to be annealed or otherwise treated before use, the specimens for tension-tests, representing such material, shall be cut from properly annealed or similarly treated short lengths of the full section of the bar.

Number of Tests. (6) At least one tension-test and one bending-test shall be made from each melt or blow of steel as rolled. In case steel differing 3/8 in and more in thickness is rolled from one melt or blow, a test shall be made from the thickest and thinnest material rolled. Should either of these test-specimens develop flaws, or should the tension-test specimen break outside of the middle third of its gauged length, it may be discarded and another test-specimen substituted therefor. In case a tension-test specimen does not meet the specification, additional tests may be made.

(c) The bending-test may be made by pressure or by blows.

Modifications in Elongation for Thin and Thick Material. (7) For material less than 5/16 in and more than 3/4 in in thickness, the following modifications shall be made in the requirements for elongation:

(d) For each increase of 1/8 in in thickness above 3/4 in, a deduction of 1 shall be made from the specified percentage of elongation.

(e) For each decrease of 1/16 in in thickness below 5/16 in, a deduction of 2½ shall be made from the specified percentage of elongation.

(f) For pins, the required percentage of elongation shall be 5 less than that specified in the tabulation of paragraph (2), as determined on a test-specimen, the center of which shall be 1 in from the surface.

Finish. (8) Finished material must be free from injurious seams, flaws, or cracks, and have a workmanlike finish.

Branding. (9) Test-specimens and every finished piece of steel shall be stamped with melt or blow-number, except that small pieces may be shipped in bundles securely wired together, with the melt or blow-number on a metal tag attached.

Variation in Weight. (10) A variation in cross-section or weight of each piece of steel, of more than 2½% from that specified, will be sufficient cause for rejection, except in case of sheared plates. These latter are covered by the following permissible variations, which are to apply to single plates:

(A) Plates, When Ordered to Weight

PLATES 12½ POUNDS PER SQUARE FOOT OR HEAVIER:

(g) Up to 100 in wide, 2½% above or below the specified weight.

(h) 100 in wide and over, 5% above or below.

PLATES UNDER 12½ POUNDS PER SQUARE FOOT:

(i) Up to 75 in wide, 2½% above or below.

75 inches and up to 100 inches wide, 5% above or 3% below.

(j) 100 in wide and over, 10% above or 3% below.

(B) Plates, When Ordered to Gauge

Plates will be accepted if they measure not more than 0.01 in below the ordered thickness.

An excess over the nominal weight corresponding to the dimensions on the order will be allowed for each plate, if not more than that shown in the following tables, 1 cu in of rolled steel being assumed to weigh 0.2833 lb.

PLATES ¼ INCH AND OVER IN THICKNESS

Thickness ordered, in	Nominal weights, lb per sq ft	Width of plate			
		Up to 75 in %	75 in and up to 100 in %	100 in and up to 115 in %	Over 115 in %
¼	10.20	10	14	18	....
5/16	12.75	8	12	16	....
⅜	15.30	7	10	13	17
7/16	17.85	6	8	10	13
½	20.40	5	7	9	12
9/16	22.95	4½	6½	8½	11
⅝	25.50	4	6	8	10
Over ⅝	.....	3½	5	6½	9

PLATES UNDER ¼ INCH IN THICKNESS

Thickness ordered, in	Nominal weights, lb per sq ft	Width of plate		
		Up to 50 in %	50 in and up to 70 in %	Over 70 in %
⅛ up to 5/32	5.10 to 6.37	10	15	20
5/32 up to 3/16	6.37 to 7.65	8½	12½	17
3/16 up to ¼	7.65 to 10.20	7	10	15

Inspection. (11) The inspector representing the purchaser shall have all reasonable facilities afforded to him by the manufacturer to satisfy him that the finished material is furnished in accordance with these specifications. All tests and inspections shall be made at the place of manufacture, prior to shipment.

Additional Paragraphs. The general specifications for a building of ordinary construction should include in addition to the above, governing the quality and tests on the material, paragraphs giving specifications for:

(1) The exact scope of the work embodied in the contract.

(2) Provision for the inspection of material and workmanship, stating specifically who is to bear the expense of the inspection.

(3) Special tests; for example, tests of full-size eye-bars.

(4) Size, limiting pitch and allowable stress for shop-rivets and field-rivets.

(5) Cleaning of surfaces and shop-painting.

6. Tension-Members

Angles. The best section for tension-members of relatively small size depends greatly on the kind of end-connections used. Angles or channels are generally used for riveted connections. For very small members rectangular bars, such as lacing-bars, may be used. The strength of such members is computed on the net area through the rivet-holes. Angles used in tension should have lugs riveted to the outstanding legs and the tie-plate for the better distribution of the stress over the section. Tests on angles with riveted connections reported by F. P. McKibben* gave from 77 to 86% of the strength of the material as shown by

* Proceedings of the American Society for Testing Materials, Vol. VI.

tension-tests on standard specimens cut from these angles. Lugs increased the strength from 4.7 to 8.7%. It was also shown that a connection giving the center of the pull on the center of gravity of the section gave considerably higher strengths than when the center of pull was in line with the gauge-line of the rivets. In computing the NET SECTIONAL AREA as reduced by rivet and bolt-holes Table XI will be found very convenient.

Eye-Bars are used for the main tension-members of pin-connected trusses. They are rectangular in section with a forged head upset in dies and of the same thickness as the bar. The eye is accurately drilled in position in the axis of the bar, true to diameter and exact central distance. Because of its advantages for forging, soft steel is used in making eye-bars. They are also carefully annealed before drilling. Table VI gives the dimensions of STANDARD EYE-BARS manufactured by the mills of the American Bridge Company. These bars are of practically the same dimensions as the standard bars of other companies. There is from 34 to 42% excess material in the section through the eye to insure in the forged part the development of the full strength of the body of the bar. Standard bars should be used in design to avoid the expense of making special dies in which to form the heads. Bars of less than the given minimum thickness are liable to fail, when loaded, by buckling in the head. Thick bars increase the BENDING-STRESSES in the pins and thus, indirectly, the necessary size of the eye. Except for very large structures they are limited to about 2 in.

Tests of Full-Size Eye-Bars are generally required when a great number of them are to be used in a structure, one in every fifty bars being usually tested. The specifications for carbon-steel bars require that an ULTIMATE TENSILE STRENGTH of 56 000 lb per sq in shall be developed, that the ELONGATION in the whole length shall be 10% and that failure shall occur in the body of the bar. Nickel steel has been used for tension-members on a few long-span bridges. The WORKING STRESS on the eye-bars was increased about one-half over that used for

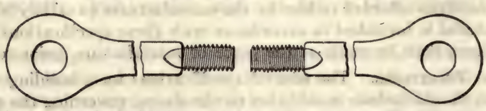

Fig. 3. Eye-bar with Screw-ends for Sleeve-nut or Turn-buckle

carbon steel, and the requirements of the test-bars made correspondingly severe. The eye is made 1/50 in greater than the diameter of the pin. Bars packed on the same pins are drilled at the same setting so as to be of exactly the same length. Bars must be true to length within 1/32 in. Small eye-bars are sometimes made with UPSET SCREW-ENDS and SLEEVE-NUTS or TURNBUCKLES in the middle for adjustment, as shown in Fig. 3 and Table VI, page 395.

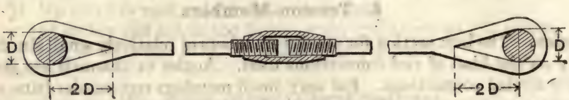

Fig. 4. Loop-eyes and Sleeve-nuts

Loop-Rods (Fig. 4, and Table VII) of round or square section with welded loop-ends are used for counterties and bracing. Because of the weld they are not so dependable as other types of tension-members, but, because of the adjustment, are well adapted for this service as secondary members.

A Forked-Loop Rod, Fig. 5, may be used for one of two tension-rods so as to avoid eccentricity where two rods balance each other on a pin. A CLEVIS at each end of one of the rods accomplishes the same object.

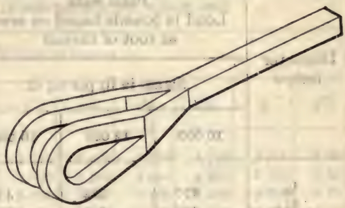

Fig. 5. Forked Loop

Turnbuckles and Sleeve-Nuts. The dimensions of these for adjusting the lengths and initial stress in ties are given in Table VIII, page 397. The open turnbuckle has the advantage of being easily inspected to note that the thread has sufficient bearing and that the ends of the rods do not butt together.

Upset Screw-Ends are threaded enlargements on the ends of rods or bolts designed to give to the threaded portions a strength as great as that of the body of the bar. Because of effects of forging it is necessary to make the area of the cross-section of the upset end at the root of the thread a little larger than that of the rod itself. A standard upset rod will fail in the body of the bar without damaging the threaded portion enough to prevent the turning of the nuts. The dimensions given are nearly the same with all manufacturers. If upset rods can not be obtained the section-area at the root of the thread must be used in computing the safe load.

Clevises. Table IX, page 398, gives the dimensions and other details for clevises according to the latest standards of the American Bridge Company.

Tables. The following tables will be found useful in designing tension-members, or for drawing turnbuckles, sleeve-nuts, clevises, etc. The strength of plain rods in Table II is based on the area at the root of the thread. For lengths and weights of tie-rods and anchors for steel beams, see Table XIX, Chapter XV.

Table II. Safe Loads in Pounds on Round Rods

REMARKS. As upsetting reduces the strength of iron, bars having the same diameter at the root of the thread as that of the bar invariably break in the screw-end when tested to destruction, without developing the full strength of the bar. It is therefore necessary to make up for this loss in strength by an excess of metal in the upset screw-ends over that in the bar.

Table V is the result of numerous tests on finished bars made at the Keystone Bridge Company's Works in Pittsburgh, Pa., and gives proportions that will cause the bar to break in the body rather than in the upset end.

The screw-threads in the above table are the Franklin Institute standards.

To make one upset end for a 5-in length of thread, allow 6 in in length of rod, additional.

* See also Table I, Chapter XX and paragraph, Punching Rivet-Holes, page 414.

7. Wire

Manufacture. Iron and steel wires are made from BILLETS about 4 in square. These are rolled into long rods which are dipped in acid to remove the scale and furnish lubrication for the drawing process. This consists in pulling the rods while cold through steel dies having a series of holes of gradually decreasing diameters. The cold working of the metal hardens it and makes it brittle so that it is necessary to anneal it at intervals during the process. The drawing increases the strength of the material, so that wires of different sizes, although made of the same material, differ greatly in ULTIMATE STRENGTH.

Finish. The common grades of iron and steel wire are furnished in several different finishes: plain black, bright tinned, copper-coated, japanned and with single and double coats of zinc galvanizing. The last is applied by passing the wire through the melted zinc which is deposited as a coating and forms one of the best-known protections against corrosion.

Wire-Gauges. Table XIII gives, according to several GAUGES, the diameters of the different numbers of wire that have come into use for different purposes and have been brought out by different manufacturers. In ordering wire by number it is best to specify which GAUGE is meant.

Strength. Table XIV gives the sizes according to the J. A. Roebling's Sons Company gauge, with the weight and length and the strength on an assumed basis of 100 000 lb per sq in. The different kinds of wire vary so widely in ULTIMATE STRENGTH, on account of both the difference in quality of the material and the effect of the drawing, that in order to obtain the approximate strength of a

wire, reference must be made to Table XII in connection with the foot-note to Table XIV. The following table is arranged from values given in the Catalogue of the J. A. Roebling's Sons Company:

Table XII. Approximate Ultimate Strength of Different Sizes of Iron and Steel Wire

Kind of wire	Ultimate strength	
	Large size lb per sq in	Small size lb per sq in
Soft iron	45 000	60 000
Telegraph and telephone (steel)	60 000	80 000
Special aviator	247 000	285 000
Piano wire	307 000	340 000
Plough steel wire	200 000	345 000
Hard-drawn copper trolley wire	50 000	not used
Hard-drawn telegraph and telephone copper	56 000	66 000

* Now the American Steel and Wire Company.

The United States Standard Gauge was legalized by Act of Congress, March 3, 1893, as a standard gauge for sheet and plate iron and steel, and is used by the Custom-House Department and by sheet-plate and tin-plate manufacturers.

Table XIV. Weight, Length and Strength of Steel Wire

Gauge of J. A. Roebling's Sons Company

Number, Roebling gauge	Diameter in	Area sq in	Breaking-load in pounds at rate of 100 000 lb per sq in	Weight in pounds		Number of feet in 2 000 pounds
				Per 1 000 ft	Per mile

13	0.092	0.006648	665	22.3	118	89 525
14	0.080	0.005027	503	16.9	89.2	118 413
15	0.072	0.004071	407	13.7	72.2	146 198
16	0.063	0.003117	312	10.5	55.3	191 022
17	0.054	0.002290	229	7.70	40.6	259 909
18	0.047	0.001735	174	5.83	30.8	343 112
19	0.041	0.001320	132	4.44	23.4	450 856
20	0.035	0.000962	96	3.23	17.1	618 620

This table was calculated on a basis of 483.84 lb per cu ft for steel wire. Iron wire is a trifle lighter.

The breaking strengths were calculated for 100 000 lb per sq in throughout, simply for convenience, so that the breaking strengths per square inch of wires of any strength may be quickly determined by multiplying the values given in the table by the ratio between the strength per square inch and 100 000. Thus, a No. 15 wire, with a strength per square inch of 150 000 pounds, has a breaking strength of

$$407 \times \frac{150\,000}{100\,000} = 610.5 \text{ lb.}$$

It must not be inferred from this table that steel wire invariably has a strength of 100 000 lb per sq in. As a matter of fact its strength ranges from 45 000 lb per sq in for soft, annealed wire to over 400 000 lb per sq in for hard wire.

8. Wire Rope

Kinds of Wire Rope. There are several kinds of WIRE ROPE in common use. In each there are three or more qualities depending on the kind of wire used and the kind of core about which the strands are laid. The Trenton Iron Company lists the following:

(1) **Haulage or Transmission-Rope,** composed of six strands of seven wires each, laid about a hemp core. It is used for haulage, transmission of power, in places where surface-wear is of chief consideration and where sheaves of sufficient diameter may be used.

(2) **Hoisting-Rope,** composed of six strands of nineteen wires each. It is used for elevator service, shafts and derricks, and in places where it is not subject to abrasion and where flexibility is of chief consideration.

(3) **Seale Rope,** composed of six strands of nineteen wires each, the inner coils of the strands being of finer wire. It is intermediate in flexibility between the first and second kinds of rope.

(4) **Non-Spinning Hoisting-Rope,** having eighteen strands of seven wires each. Twelve of the strands are laid in reverse direction to the inner six, making it well adapted for hoisting in free suspension without untwisting and turning the load.

(5) **Extra-Flexible Hoisting-Rope,** having eight strands of nineteen wires each.

(6) **Special Flexible Hoisting-Rope,** having six strands of thirty-seven wires each.

(7) **Hawser-Rope and Flexible Running-Rope,** having six strands of twelve galvanized wires each, laid about a hemp core.

(8) **Tiller-Rope,** composed of six small seven-strand ropes laid about a hemp core. It is the most flexible of wire ropes and is used to operate tillers and for hand-ropes in elevators.

The Lay of Wire Rope is the twist of the wires in the strands relatively to the strands in the rope. In the ORDINARY LAY the twist of the strands is the reverse of that of the wires, while in the LANG LAY the strands are laid in the same direction as the twist of the wires. This latter gives a greater distribution of the wearing-surface and a somewhat greater flexibility; but it has the disadvantage of a tendency to untwist and for this reason should not be used for hoisting weights in free suspension. Wire rope is also made up in FLAT or RIBBON FORM. For large sizes it is more flexible than standard rope and may be run over smaller drums.

Materials for Rope. Nearly all of the above kinds of rope are made up in the following materials:

(1) **Best Grade of Wrought Iron.** This is used in high-speed PASSENGER-ELEVATOR SERVICE as it seems to suffer less from the effects of the stresses due to the starting and stopping of the cars.

(2) **Cast-Steel Wire,** with an ultimate strength of from 160 000 to 210 000 lb per sq in, according to the size used.

(3) **Extra-Strong Cast-Steel Wire,** with an ultimate strength of from 190 000 to 230 000 lb per sq in.

(4) **Plow-Steel Wire** with an ultimate strength of from 200 000 to 230 000 lb per sq in.

Ordinary GALVANIZED-WIRE ROPE should not be used for other than standing rope. A short service running through sheaves will break the coating and permit

Table XV. Strength of Wire Rope

Arranged from the 1912 list of John A. Roebling's Sons Company

Trade number	Diameter inches	Weight per foot, hemp core	Approximate breaking-load in pounds		Minimum diameter of drum or sheave in feet

25	9/32	0.125	2 400	5 000	3	1.75

The working load is to be taken at one-fifth the breaking-load. This is assumed in calculating the diameter of the sheaves.

rapid corrosion of the rope. Because of the many kinds and qualities of rope it is well to consult the manufacturers as to which kind will best suit the conditions for any particular service. The John A. Roebling's Sons Company, Trenton, N. J., the Trenton Iron Company, Trenton, N. J., and A. Leschen & Sons Rope Company, St. Louis, Mo., are among the largest manufacturers of full lines of ropes.

Coils. Wire rope should not be coiled like hemp rope, and in order to avoid kinking, should be taken from the reels without twisting. If it is not shipped on a reel, to avoid injury it must be rolled over the ground like a wheel.

Lubrication. It is very important that running ropes be properly lubricated, since, if proper care is not taken, the wear on the interior parts, between the wires, may be almost as great as the outside abrasion. The oil should penetrate to the core of the rope and yet not drip off a few days after application. Information as to the care of rope may be obtained of the Wire Rope Lubricating Company, Newark, N. J.

Sheaves. The size of sheaves recommended in the tables are calculated for a working-load of one-fifth the given breaking-load. If smaller sheaves are used the life of the rope will be greatly shortened, because of the excessive bending of the outer wires.

Table XVI. Galvanized, Steel-Wire Strands

For guys, signal-cords, trolley-line span wire, etc. Taken from the Trenton Iron Company's full list

Diameter in inches	List-price per 100 feet	Weight per 100 feet	Approximate breaking-load in pounds
5/8	$7.25	80	14 000

9. Cotton, Hemp and Manila Rope

Rope is made of cotton, hemp, and Manila fiber. Cotton is used for small sizes, only, and for such purposes as sash-cord, etc.

Manufacture. In the manufacture of rope the fiber is first spun into YARN. From twenty to eighty threads are twisted together into STRANDS and the strands, three or four, are laid together, opposite in direction to the TWIST in the strands, but in the same direction as the THREADS. This causes the fibers to be twisted as the rope untwists and produces a balancing of forces that tends to keep the rope in shape.

Cables and Hawsers are made up of strands of rope.

Rope used for Hoisting wears rapidly from the action of the pulleys and also from the bending which causes a slight internal motion between the fibers and a chafing and grinding away of the interior.

Stevedore-Rope, of the C. W. Hunt Company, is filled with a tallow and plumbago lubricant which decreases the internal friction, lubricates the outside of the rope and thus greatly prolongs its life.

Strength. The values of the strength of new rope, given in Table XVII, are taken from the Specifications of the United States Navy Department, issued in June, 1910, at the Boston Navy-Yard. Manufacturers generally adopt these sizes and weights and claim a strength equal to or a little greater than the values given. The UNIT STRENGTH for the different sizes varies, being about 14 000 lb per sq in for the smaller and about 10 000 for the largest size. The approximate formula, offered by C. W. Hunt, of 720 times the square of the circumference in inches, is equivalent to about 9 000 lb per sq in. American hemp, tarred, has about 5% greater strength than Manila rope of the same size. The navy specifications give for two-strand American-hemp rope, 85% of the strength of the three-strand rope of the same material.

7	2.22	1.63	36 200	....	......
8	2.54	2.17	47 300	....	......
9	2.87	2.70	60 000	....	......
10	3.14	3.33	74 200	....	......

Manila-hemp rope is made in three strands and in sizes up to 3 in in circumference; four strands are used for sizes larger than 3 in in circumference.

Working Load. The WORKING LOAD for slow-speed derrick and hoisting-service is usually taken at one-seventh the BREAKING-LOAD. This makes some allowance for the loss of strength at splices and connections. The deterioration of rope exposed to the weather is very rapid. For Manila rope from 1 to 1¾ in in diameter, running over sheaves of the diameters given, C. W. Hunt in Trans. Am. Soc. M. E., Vol. XXIII, gives a table embodying approximately the following results of experience:

Table XVIII. Working Loads for Manila Rope

Working load = $C \times$ breaking-load of new rope

D = minimum diameter of sheave in inches

Speed	Feet per minute	Kind of work	Value of C	D for rope of diameter of	
				1 in	1¾ in
Slow......	50 to 100	Derrick, crane, quarry, etc.	0.014	8	14
Medium...	150 to 300	Wharf, cargo, etc.	0.056	12	18
Rapid.....	400 to 800	....	0.028	40	70

The wear in such service is very rapid, a 1½-in rope wearing out in lifting from 7 000 to 10 000 tons of coal. On the other hand, a 1½-in transmission-rope running at 5 000 ft per min and carrying 1 000 horse-power over sheaves 5 ft and 17 ft in diameter, lasts for years, the difference being due to the smaller stress and larger sheaves.

10. Chains

Manufacture. Chains are made by hand-welding from best wrought-iron bar. The bending and welding reduce the strength so that the chain is not twice but only from 1.55 to 1.70 times as strong as the original bar from which it was made. STUD-CHAIN having a bar welded across each link to stiffen it and prevent fouling in handling, is not as strong as OPEN-LINK CHAIN. G. A. Goodenough, in a Bulletin from the Illinois Engineering Experiment-Station finds that the stud-chain will support a greater load at the ELASTIC LIMIT of the material. If P is the load, d the diameter of the bar and S the stress, the formulas are:

$$P = 0.5\, d^2S \text{ for the stud-chain, and}$$
$$P = 0.4\, d^2S \text{ for the open-link chain.}$$

Proof-Tests. A proof-test is applied to chains by the manufacturers. The load applied is one-half the average BREAKING-LOAD. It serves to detect bad welds and gives a chain a slight permanent set, so that for working loads thereafter there will be little stretching of the chain. The ordinary WORKING LOAD should not be greater than one-third the breaking-load.

Care of Chains. Chains in constant use require lubrication and frequent annealing. They harden in service and are liable to unexpected failure if not annealed. It is recommended that hoisting-chains and sling-chains be annealed at least once a year. It is also very important that the ordinary SAFE WORKING STRESS be not exceeded.

Table XIX. Sizes, Weights, Proof-Tests and Average Breaking-Loads for Chains

Bradlee and Company, Philadelphia

Size of chains in	Approximate weight per foot	D.B.G. special crane		Crane	
		Proof-test lb	Average breaking-load lb	Proof-test lb	Average breaking-load lb
¼	¾	1 932	3 864	1 680	3 360
⅜	1½	4 186	8 372	3 640	7 280
½	2.5	7 728	15 456	6 720	13 440

Strength of Old Iron. A square link 12 in broad, 1 in thick, and about 12 ft long was taken from the Kieff Bridge, then forty years old, and tested in comparison with a similar link which had been preserved in the stock-house since the bridge was built. The following is a record of a mean of four longitudinal test-pieces, 1 by 1⅛ by 8 in, taken from each link.

Table XXI. Strength of Old Chain-Links*

	Old link from bridge	New link from stock-house
Tensile strength per sq in, tons	21.8	22.2
Elastic limit per sq in, tons	11.1	11.9
Elongation, per cent	14.05	18.42
Contraction, per cent	17.35	18.75

* Taken from the Mechanical World, London.

CHAPTER XII

RESISTANCE TO SHEAR. RIVETED JOINTS. PINS AND BOLTS

By
HERMAN CLAUDE BERRY
PROFESSOR OF MATERIALS OF CONSTRUCTION, UNIVERSITY OF PENNSYLVANIA

1. Shear

Shear is the internal stress in a body which resists the tendency of two adjacent parts to slide on each other, due to the action of two equal and parallel external forces, called SHEARING-FORCES, acting on opposite sides of the plane of shear.

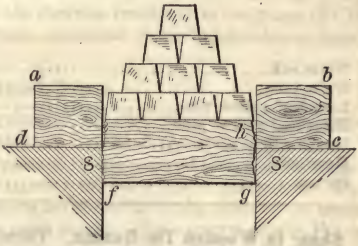

Fig. 1. Shearing-failure of Beam

If the piece *abcd* of Fig. 1 represents a short simple beam of brittle material on which a sufficient load is applied, it will fail in VERTICAL SHEAR at *f* and *g*, as shown, by a sliding on the sections of the beam at these points, because the upward force of the reaction at *S* and the downward force of the load adjacent to *S*, against which it acts across the section at *S*, is greater than the total SHEARING RESISTANCE of the section. Shear is present over the entire length of the beam and at any section is equal to the reaction at *S* minus the weight of the load between the reaction and the section in question. In general, the VERTICAL SHEAR at any section of a beam subjected to vertical loads is equal to the algebraic sum of all the vertical forces acting on the beam on either side of the section.

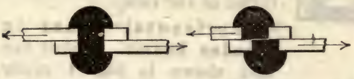

Fig. 2. Example of Single Shear

Single and Double Shear. A rivet connecting two bars under tension (Fig. 2) is subjected to a SHEARING-STRESS. If one section of the rivet transmits the force the rivet is said to be in SINGLE SHEAR; if two sections, it is in DOUBLE SHEAR.

Distribution of Shear. Shear is considered to be UNIFORMLY DISTRIBUTED over the section except in cases of torsion and of complex stresses.

For the ordinary cases of shear in rivets, etc., if

S_s = the allowable unit stress in shear,
A = the area under stress,
and P = the safe shearing-load;
then

$$P = AS_s \tag{1}$$

The Ultimate Strength in Shear has been determined for building materials by testing suitably prepared specimens and dividing the maximum load ob-

served by the area under stress. For material like wood, in which there are planes of weakness, tests must be made which take these into account. The direction of the force with respect to these planes must be considered in choosing the SAFE WORKING STRESS from the tables.

Safe Working Stresses in Shear. Table I gives SAFE WORKING STRESSES in SHEAR for those building materials usually subjected to such stresses.

Table I. Safe Working Stress in Shear for Building Materials

Material	Safe stress in lb per sq in	
Cast iron (New York)	3 000	
Wrought iron	7 500	
Steel, bolts, rivets	10 000 (average)	
	With the grain	Across the grain
White oak	200	1 000
White pine	100	500
Long-leaf yellow pine	150	1 250
Short-leaf yellow pine	130	1 000
Douglas fir	130	900
Hemlock	100	600
Spruce	100	750

Shear in Wooden Tie-Beams. There are a few cases in architectural construction in which the weakness of wood in shear must be provided for. The one most frequently arising is the framing of the end of the tie-beams in wooden trusses.

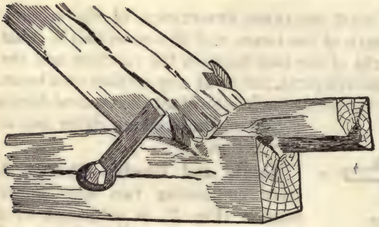

Fig. 3. Shearing-failure in Wood

Fig. 3 was made from a photograph of a SHEARING-FAILURE of a tie-beam from the thrust of the rafter.

Horizontal Shear in Wooden Beams. Failure like that shown in Fig. 1 rarely occurs in wood; but rectangular wooden beams, the length of which is less than about twenty times the depth, are liable to fail by HORIZONTAL SHEAR along the middle, under about the same loads that cause the allowable working stresses in bending.

Shear at the End of a Tie-Beam. In the case of the truss-joint (Fig. 4), the thrust S of the rafter tends to shear off the part $ABCD$ along the plane of which CD is the trace. This area under stress must offer a SHEARING RESISTANCE equal to the horizontal component H of the thrust S. The width of the beam b, being fixed, formula (1) gives

$$H = (CD \times b)S_s \quad \text{or} \quad CD = H/bS_s$$

The shear being in the same direction as the grain of the wood, the lower value in Table I must be used.

Example 1 (Fig. 4). The horizontal component of the thrust of a rafter is 20 000 lb. The long-leaf yellow pine tie-beam is 10 in wide. How far should the beam extend beyond the point D?

Solution. In this case $H = 20\,000$ lb. From Table I, $S_s = 150$ lb per sq in. Then $CD = \frac{20\,000}{10 \times 150} = 13.3$ in and should be made at least 13½ in.

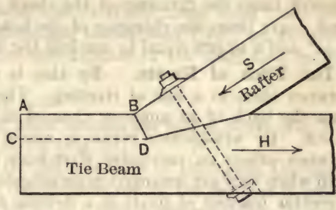

Fig. 4. Truss-joint

As actually constructed a large part of the thrust is generally taken up by a bolt or strap at the foot of the rafter to hold it in place. As the bolt and shoulder seldom act together, either the length CD on the tie-beam should be made long enough to resist the entire thrust, or the bolt or strap designed to do so without relying on the shearing resistance in the plane of CD. The design of such joints is more fully considered under Subdivision 4, pages 429 to 439 of this chapter.

2. Riveted Joints

Use of Rivets. Rivets almost exclusively are used in connecting the plates and shapes which make up the members of framed steel construction.

Rivet-Definitions. A rivet is a piece of cylindrical rod with a HEAD forged on one end and usually with a slight taper at the other end of the SHANK. The grip (Table IV) of the rivet is the length betweeen the under sides of the heads after driving, or the thickness of the parts joined. The LENGTH (Table IV) of the rivet is equal to the grip plus enough of the stock to form a head, and is measured from the end of the shank to the under surface of the head. The DIAMETER OF THE SHANK of a rivet is made equal to its NOMINAL DIAMETER, but rivets are driven into holes ⅛ in larger in diameter and upset by the driving so as to completely fill the holes. The shearing values and bearing values are based upon the NOMINAL AREA and not upon the area of the hole.

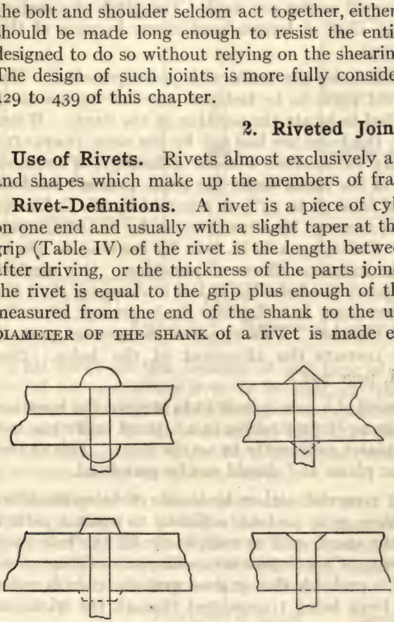

Fig. 5. Forms of Rivet-heads

Riveting consists in heating the rivet to a welding-heat, passing it through holes in the parts to be joined and forging another head out of the projecting shank. This may be done by hand-hammering; but shops use compressed-air-operated hand-hammers or large riveting-machines which form the head and cause the shank to completely fill the hole by heavy pressure on a die.

Material of Rivets. Rivets are made of soft steel and of wrought iron. Rivet-steel is generally used. The head may have any of the forms shown in Fig. 5, although the first, called the BUTTON-HEAD, is the standard for structural work. The fourth or COUNTERSUNK HEAD is used where it is necessary to have a flat surface, as over a bearing-plate.

The Sizes of Rivet-Heads differ slightly at different mills. The Standards of the American Bridge Company give for the DIAMETER OF THE HEAD, one and one-half times the diameter of the shank plus 1/8 in, and for the HEIGHT of the head, 0.425 times the diameter of the head. Countersunk heads have a SLOPE of 30° and a DEPTH equal to one-half the diameter of the shank.

The Pitch of Rivets. By this is meant the center-to-center distance between them in a line of riveting. The distance between lines of rivets, or from the back of an angle or channel to a rivet-line is called the GAUGE-DISTANCE. By STAGGERED PITCH is meant the arrangement of rivets midway between others on successive rivet-lines in order to decrease the section less than when they are arranged in rectangular rows, and at the same time to place a greater number of rivets in a definite area. The PITCH should not be made less than three diameters of the rivet and the DISTANCE FROM THE EDGE of the plate not less than one and one-half diameters, although it may be necessary to make the distance less when small angles are used. The pitch of countersunk rivets must be greater than that of button-head rivets because of the greater amount of material removed.

Punching Rivet-Holes. Rivet-holes are made with power-punches. The SPACING is marked on the different parts to be fastened together by means of wooden templates with holes drilled to locate the position of the rivets. When the different parts are assembled, the holes are laid out by the same TEMPLATE-REGISTER, so that the rivets may be inserted without difficulty. PUNCHING makes a ragged hole. The flow of the metal under the great pressure hardens it and causes a loss in strength of from 11 to 33% as reported by W. C. Unwin for soft steel. The injury may be removed by ANNEALING or by REAMING away the injured part of the metal. Enlarging a 7/8-in. hole by reaming to 1 1/8 in has been found to remove all the injurious effects of punching. One method practiced in the best work is to punch the holes 1/16 in less in diameter than the diameter of the rivets, and to ream them to a diameter 1/16 in greater, after the parts are assembled and bolted together. This removes the greater part of the injury from punching and corrects the alinement of the holes. (See Table XI, page 400, and Table I, page 702.)

Drift-Pins. When the alinement of a hole is such as to prevent the insertion of the rivet, it is the practice in some shops to drive in a tapered DRIFT-PIN and distort the holes in some of the plates sufficiently to set the rivet. This causes LOCAL STRESSES and injury to the plates and should not be permitted.

Shop-Riveting is done with powerful air or hydraulic riveting-machines which may exert a pressure of from 30 to 50 tons, sufficient to upset a perfect head on the projecting end of the shank and to completely fill the hole even though the alinement is imperfect. Contraction on cooling causes great pressure between the parts, so that it is probable that in good work the rivet is under little or no shearing-stress, the force being transmitted through the frictional resistance of the plates.

Clearance. It is important that the designer place the rivets so they may be inserted from one side and pounded on the other for HAND-WORK, or so that the machine may reach them for MACHINE-RIVETED WORK. For example, the minimum distance from the inside face of the leg of one angle to a line of rivets in the other leg must not be less than 1 1/8 in for 7/8-in rivets, 1 in for 3/4-in rivets, etc. In general, a distance 3/8 in greater than the diameter of the head should be allowed for CLEARANCE.

Inspection. The common imperfections in riveting are LOOSE RIVETS and ECCENTRIC HEADS. Loose rivets may be detected by holding the hand against

one side of the rivet-head and tapping the other side with a light hammer. If loose, a slight slip may be felt. The loose rivets should be marked to be cut out and replaced. The inspector should also carefully check open holes left for field-connections, and see that flattened and countersunk rivets are as called for, because such work may be done at less expense in the shop than in the field, where it may cause delay.

The Failure of Riveted Joints may occur

(1) In TENSION, by the tearing of the plate through the line of rivets (Fig. 8).

(2) In SHEAR, by the cutting of the rivets (Fig. 7).

(3) In BEARING, by the crushing of the plate in front of the rivets, the splitting of the plate, or, in some cases, by the shearing out of the sections in front of the rivets. In a careful design of a joint the strength against failure by each of these methods must be investigated (Fig. 6 and Fig. 9).

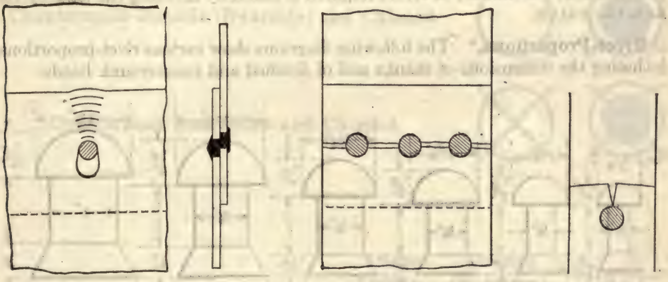

Fig. 6 Fig. 7 Fig. 8 Fig. 9

Figs. 6 to 9. Methods of Failure in Riveted Joints

The Steps in the Design of any type of riveted joint are, (1) the selection of the size of the rivet to be used, (2) the determination of its shearing and bearing strength and the use of the smaller value of the two to divide into the total load to be transmitted and thus determine the number of rivets, (3) the arrangement of the rivets in the plate and the investigation of its strength in tension at the dangerous section.

The Size of Rivets is determined in part by SHOP-PRACTICE. Holes cannot be punched in plates which are thicker than the diameter of the punch. The following table gives the size of rivets used with plates of different thickness. Some specifications for structural work require all rivets to be ¾ in, except where thick plates require larger ones.

Thickness of plates	Size of rivets
¼ to 7/16 in	⅝ in
½ to ⅝ in	¾ in
11/16 to 13/16 in	⅞ in
⅞ to 1 in	1 in

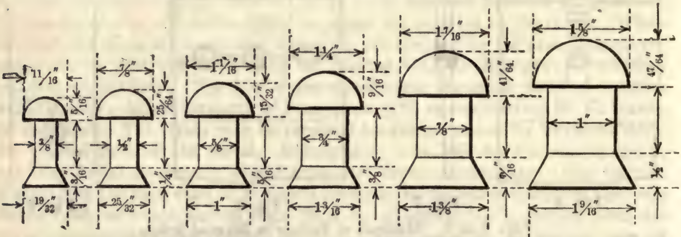
Tables II and III give the SHEARING and BEARING VALUES for different sizes of rivets in plates of different thickness for two values of working stresses each; shear at 7 500 and 10 000 lb per sq in and bearing at 15 000 and 18 000 lb per sq in. Values for higher stresses can be figured by proportion from these tables. The lower stresses should be used with wrought iron or in parts subjected to live loads; the higher stresses where only constant or dead loads are present.

The SHEARING VALUE is equal to the area of the rivet multiplied by the working stress; the BEARING VALUE is equal to the area of the projected surface under pressure multiplied by the working stress in bearing, or, if

t = the thickness of the plate;
d = the diameter of the rivet;
and S_b = the working stress in bearing;
then the bearing value $P = dtS_b$ (2)

The Shearing and Bearing Values may be taken directly from the tables, and if a rivet is in double shear, twice the quantity in the table is to be used for its SHEARING VALUE. Quantities above the heavy broken lines are BEARING VALUES greater than the values in single shear, so that for these conditions, the number of rivets necessary in a joint required to transmit a certain load is determined by dividing the load by the value in single shear. If rivets are in, double shear, the number of rivets required is found by dividing the load by the BEARING VALUE.

Rivet-Proportions.* The following diagrams show various rivet-proportions, including the dimensions of shanks and of finished and countersunk heads:

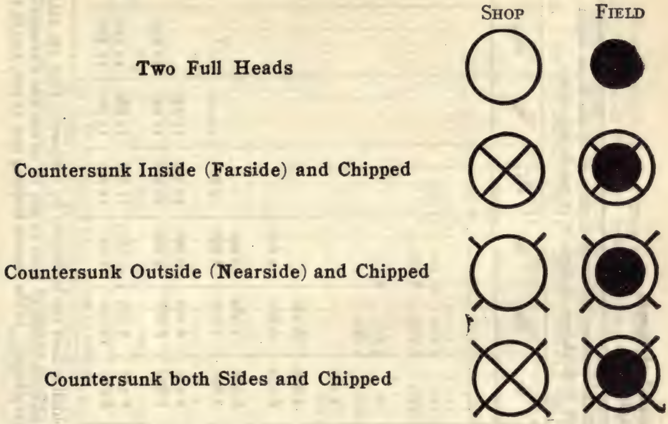


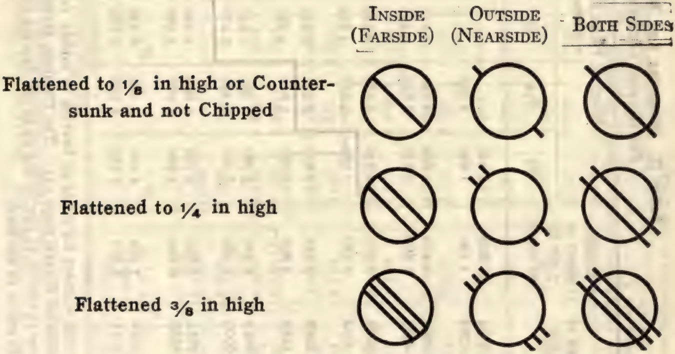
Diam. head = 1½ diam of shank + ⅛" depth of head = 45/100 diam of head

Depth of head = ½ diam of shank. Bevel of head = 60°

* These proportions vary slightly at different mills and in different handbooks.

Conventional Signs for Riveting. The following diagrams show some conventional signs for riveting:





This system, designed by F. C. Osborn, has for its foundation a diagonal cross to represent a countersink, a blackened circle for a field-rivet and a diagonal stroke for a flattened head. The position of the cross with respect to the circle, inside, outside, or on both sides, indicates the location of the countersink; and similarly, the number and position of the diagonal strokes indicate the height and position of the flattened heads. Any combination of field, countersunk and flattened-head rivets liable to be used may be readily indicated by the proper combination of the above signs.

Table II. Shearing and Bearing Values* of Rivets
For Riveted Girders and Wrought Iron

* Values for higher or lower unit stresses for shear or bearing to satisfy particular building laws can be figured by proportion from the table. See, also, paragraph on Working Stresses for Rivets, page 423. The Cambria Handbook (1912) gives values of from 12 000 to 20 000 and Carnegie's Pocket Companion (1915) values of from 14 000 to 24 000 lb per sq in for bearing for various structures. In the Boston building law 18 000, and in the New York City building law 20 000 lb per sq in are used.

For weight of rivets, see page 1442.

Use of Riveted Joints. Riveted joints are used in building-construction (1) in tie-bar splices, (2) in floor-beam connections, (3) in the joints of trusses, (4) in riveted girders, and (5) in column-connections.

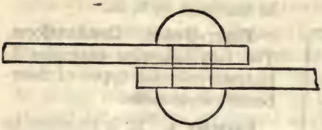

Fig. 10. Lap-joint

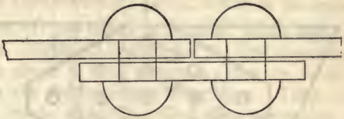

Fig. 11. Butt-joint with Single Cover-plate

Splicing of Tie-Bars. Tie-bars may be spliced by a LAP-JOINT (Fig. 10); by a BUTT-JOINT with a single cover-plate (Fig. 11); or by a BUTT-JOINT with two cover-plates (Fig. 12).

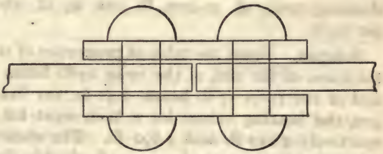

Fig. 12. Butt-joint with Two Cover-plates

The Butt-Joint is symmetrical and more efficient than the others because of the absence of any tendency to bend when under a load. The net area of the cover-plates at the section through the rivets at the end of the main plate must be equal to the net area of the main plate through the rivets at the end of the cover-plate. Fig. 14 shows a better arrangement of rivets than that in Fig. 13, because less area is removed at the critical section of the cover-plates. In some cases it may be necessary to make the aggregate thickness of the cover-plates greater than the thickness of the main plates.

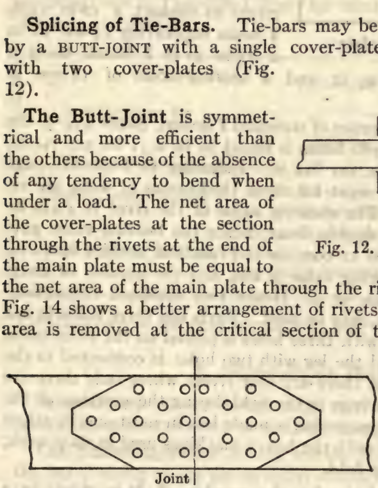

Fig. 13. Cover-plate. Six Rivets at Critical Section

A joint with one line of rivets is said to be SINGLE-RIVETED, one with two lines DOUBLE-RIVETED, and one with more than two lines, CHAIN-RIVETED.

Example 2. It is required to determine the number of rivets in the splice of a 12 by ½-in tie-bar which is subject to a tensile force of 65 000 lb.

Solution. Assuming that the load is constant, the stresses in Table III may be used. Assuming, also, a lap-joint like that in Fig. 15, and ¾-in rivets, the value in shear of one rivet is found to be 4 420 lb and the bearing value against a ½-in plate, 6 740 lb. The number of rivets is determined by the shear to be equal to 65 000 divided by 4 420, or fifteen. Since sixteen rivets are required to complete a figure smaller but similar in arrangement to that shown in Fig. 15, this number is used. There is some latitude possible in the spacing of the rivets, but with a width of 12 in, the horizontal gauge-lines are placed 1½ in apart for symmetry. If the pitch P, as shown in Fig. 15, is required to be three times the diameter of the rivet, this diagonal pitch across the rivet-spacing must be 2.25 in, or

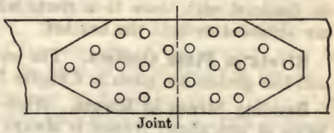

Fig. 14. Cover-plate. Four Rivets at Critical Section

greater. The length of the horizontal or third side of the right-angled triangle, having an hypotenuse of 2.25 in and a vertical altitude of 1.5 in, is 1.68 in, which requires that this distance *ED*, etc., be 1.75 in, if measured in multiples of ¼ in.

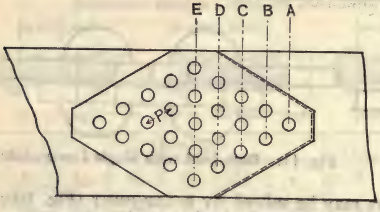

Fig. 15. Rivet-spacing in Cover-plate

Floor-Beam Connections. The two following examples illustrate common types of floor-beam connections.

Example 3. It is required to determine the number of ¾-in rivets to connect a 10-in 25-lb **I** beam supporting 24 000 lb to a 15-in 42-lb **I** beam, using a shearing-stress of 10 000 lb per sq in and a bearing-stress of 18 000 lb per sq in.

Solution. From the table of properties of standard **I** beams, pages 454–5, the thickness of the web of the 10-in 25-lb beam is found to be 0.31 in, say 5/16 in, and of the 15-in 42-lb beam, 0.41 in, say 7/16 in. Referring to Table III, page 419, the bearing values for a ¾-in rivet for these thicknesses of webs are respectively 4 210 lb and 5 890 lb. The shearing value of the rivet is 4 420 lb. The rivets in the 10-in beam are in double shear; hence the bearing value governs. The number of rivets, then, is 12 000, the end-reaction, divided by 4 210, or 3. For the 15-in beam the shearing value is less, and the number of rivets required is 12 000 divided by 4 420, or 3. Hence two standard connection-angles, 6 by 4 by ⅜ in and 5 in long, may be used. Each has three holes in one leg and two in the other. The leg with three holes is placed on the 10-in beam with the rivets in double shear, and the leg with two holes is connected to the 15-in beam; thus, in the latter case there are four rivets where only three are required for strength. They are driven in the field during the erection of the structure and the working stress is accordingly made less in most specifications because of the better work possible with the heavy machines used in shop-work, than with the tools available in the field.

Example 4. It is required to determine the number of ¾-in rivets in a 4 by 4 by ½-in angle-bracket attached to an 18-in 55-lb beam and supporting a 10 by 12-in wooden beam on which there is a load of 18 000 lb.

Solution. The rivets are in single shear with a shearing-resistance of 4 420 lb, taken from Table III. The thickness of the web of the **I** beam is 7/16 in, giving a bearing value of 5 890 lb. Dividing 9 000 lb, the end-reaction, by 4 420 lb, the controlling value, we find that two rivets are insufficient. The bracket may be fastened with three ¾-in rivets with a spacing of 4 in. Two ⅞-in rivets are sufficient to hold the bracket.

Rivets in Plate Girders. The methods of determining the rivets in plate and box girders are given in Chapter XX.

Bending Stress in Rivets. While the BENDING STRENGTH of PINS at the joints of articulated trusses is always investigated, this is never done in the case of RIVETS. A hot rivet properly driven is, when cold, under a tensile stress which is nearly equal to the elastic limit of the material. This causes great pressure between the plates and a consequent frictional resistance to movement, which, under the usual conditions, equals the allowed shearing-force on the rivet; and so, until an INITIAL SLIP occurs, there can be no BENDING STRESSES in the rivet. In the case of very long rivets driven in holes where

there is an imperfect alinement of the plates and a consequent difficulty in making the rivets fill the holes completely, it is not probable that any large bending stresses can occur in the rivets of a structure. This has been avoided in a few structures for which long TAPER RIVETS were specified to be used in holes REAMED with TAPERED REAMERS, thus insuring a perfect filling of the holes.

Working Stresses. Tables II and III are based on stresses which approximate those used in the best practice. Table II is used for the few structures made of WROUGHT IRON and for those places in steel structures that are subject to severe conditions of service, as in the floor-systems of bridges. Table III is used for ordinary structural work made under the conditions governing in modern shop-practice. For comparison, the following stresses taken from the specifications of Theodore Cooper for Steel Railroad Bridges and Steel Highway Bridges are given:

Specification for	Allowable stresses on rivets, lb per sq in	
	Bearing	Shear
Steel railroad bridges	15 000 (12 000 on floors) 22 500 for laterals	9 000 (7 200 on floors) 13 500 for laterals
Steel highway bridges	18 000 (14 400 on floor-beams) 27 000 for laterals	10 000 (8 000 on floor-beams) 14 000 for laterals

Rivets driven in the field are allowed two-thirds the value of shop-driven rivets.

3. Strength of Pins in Trusses*

Truss-Pins. In the design of the PINS at the joints of trusses the stresses in SHEAR, BEARING FLEXURE OF BENDING must be investigated.

The Shearing-Force at any section of the pin is the algebraic sum of all the forces acting on the pin on either side of the section. The stress is considered to be uniformly distributed over the cross-section of the pin. When the forces do not act in the same plane they must be resolved into vertical and horizontal components and the resultant of these components taken as the shear at any desired section. This may be done by the principles of GRAPHIC STATICS, or by TRIGONOMETRICAL and ALGEBRAICAL METHODS, the graphic method being, for some, the more rapid.

The Bearing Area on the pin is taken as the PROJECTION OF THE AREA OF CONTACT, the area of this projection being equal to the diameter of the pin multiplied by the thickness of the plate. The bearing is assumed to be uniformly distributed; hence for any load the intensity of the pressure may be decreased by increasing the thickness of the plate or the diameter of the pin.

The Bending Moments on the pin may be found by the PRINCIPLE OF MOMENTS or by methods involving the principles of GRAPHIC STATICS explained in Chapter IX in finding the bending moments of beams. The forces are considered to be concentrated at the middle of the bearing-plates. If they do not lie in a plane with the pin they must be resolved into their vertical and hori-

* Since the introduction of rolled-steel shapes and riveted joints, pin-joints for trusses in buildings have fallen into disuse. The general principles of their design, however, are given here.

zontal components and these component forces in the two planes treated separately. The resultants in both planes at any section may be combined and a single resultant force acting on the section obtained, and also the consequent stresses due to it.

Table V. Shearing and Bearing Values of Pins for One-Inch Thickness of Plate, in Pounds per Square Inch

In the Method of Moments a section is taken at each force in succession and the moment of the forces about a point in the section found, due consideration being given to the direction of turning. This is done at each force on one side of the pin, if the bars are arranged symmetrically, and in both the vertical and horizontal planes. Inspection of the results will usually indicate which section

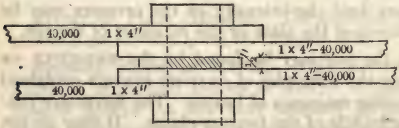

Fig. 16. Pin-joint

has the GREATEST RESULTANT MOMENT when the horizontal and vertical components, H and V, are combined. This is done by using the formula $R^2 = H^2 + V^2$ since, graphically, the resultant R is the diagonal of the rectangle

3⅞	85 700	114 200	128 500	6⅞	478 500	638 000	717 800

Remarks. The following is the formula for flexure, $M = SI/c$, with the reductions made to adapt it to a beam of circular section:

$$M = S\pi d3/32 = SAd/8$$

M = the moment of forces for any section through the pin;
S = the stress per sq in in extreme fibers of pin at that section;
A = the area of the section;
d = the diameter;
π = 3.14159.

The forces are assumed to act in a plane passing through the axis of the pin.

The above table gives the values of M for different diameters of pin, and for three values of S.

If the maximum value of M is known, an inspection of the table will show what the diameter of the pin must be so that S will not exceed 15 000, 20 000, or 22 500 lb, as the requirements of the case may be.

on H and V. Example 6 illustrates the method for the condition of INCLINED FORCES acting on the pin. In Example 5 the same method is employed to determine the size of the pin in a simple joint.

Example 5. It is required to determine the size of the pin for the joint shown in Fig. 16 in the lower chord of a steel truss. The middle bar is a vertical suspension-rod to hold the chord in place.

Solution. Beginning at the section between the outer bars, the algebraic sum of the forces on either side of the section is 40 000 lb, hence this is the shear. At the section next to the suspender the sum is zero; therefore there is no shear at the middle of the pin. The bearing pressure is 40 000 lb. Its intensity depends on the diameter of the pin and the thickness of the bars. To find the bending moment on the pin the forces are considered concentrated at the middle of the bars and moments taken about sections through the forces. The moment at the section through the second bar is 40 000 lb × 1 in, equal to 40 000 in-lb. If moments are taken about a point between the inner forces the same result is obtained. From Table VI it is found that a 2¾-in pin at 20 000 lb per sq in is sufficient. From Table V the bearing value of a 2¾-in pin is found to be only 33 000 lb at a stress of 12 000 lb per sq in, which makes it necessary to increase the size of the pin to 3⅝ in. The shearing value of this pin is 67 000 lb. In this case the diameter of the pin is determined by the bearing-stress, but it is necessary to investigate the other stresses to be sure of the correct size, especially in case of heavy bearing-plates.

Bending Moments on Pins. The finding of the BENDING MOMENT due to the forces acting on a pin is usually the most difficult part of the work of determining its proper size. In the case of a simple pin, properly packed and lying in the plane of the forces acting on it, the GREATEST MOMENT is usually the product obtained by multiplying the outer force by the central distance between the outer bars; but when the forces act in several planes the work is more complicated. The GRAPHICAL METHOD illustrated in the solution of the two following examples has some advantages; but the METHOD OF MOMENTS applied at the end of the solution of the first example is equally rapid in practiced hands and capable of greater refinement in the results.

Example 6. It is required to find the bending moment on the pin of the joint, one-half of which is shown in Fig. 17. The bars are each 1 in thick, the channel of the vertical member ½ in thick and the center of the hanger is ¾ in from the center of the channel.

Solution. Since the joint is symmetrical it is necessary to construct but one-half of the force-diagram and equilibrium-polygon which really apply to the joint. From the conditions of equilibrium of forces, the vertical component of the inclined force is upward, and equal to the sum of the downward forces, 34 000 lb; and its horizontal component acts with the 60 000-lb force, to the amount of 17 000 lb, a sufficient amount to close the force-diagram. The following construction is special, in that but one-half of the entire graphical diagram is shown. This is made possible because of the symmetry of the joint, the bending moment being constant over the middle of the pin.

In the diagram (Fig. 18) AB is drawn at an angle of 45° with the horizontal, and commencing at c, the distances are laid off to scale between the bars, and the lines 1–2, 2–3, etc., drawn parallel to the forces they represent at the joint. The oblique force is resolved into its components 1–4 and 1–5.

The stress-diagram (Fig. 19) is drawn as follows: On a horizontal line the forces are laid off to scale in the order they occur on the pin, 1–2, 2–3, 3–4 and 4–1, the closing of the diagram being a check on the correctness of the value of the forces. Beginning at 1, 1–5, 5–6 and 6–1 are laid off to scale, parallel to the forces in the vertical plane. From 1 the line 1–0 is drawn at an angle of 45°, for convenience in making good intersections, and equal to a convenient number, say 20 000 lb, in the same scale to which the loads are drawn. The

point O is the pole of the stress-diagram, the pole-distance being 20 000 lb. From the principles of graphics the bending moment at any point on the pin is equal to the intercept between the proper ray of the equilibrium-polygon and the closing line, multiplied by the pole-distance. To complete the figures, 0–2, 0–3 and 0–4 are drawn from O, and from c cd is drawn parallel to 0–2, de parallel to 0–3, ef parallel to 0–4 and fk parallel to 0–1. In the same way rs is drawn parallel to 0–5, st to 0–6 and tv to 0–1. Then according to the above principles, the moment at any section due to the forces in the horizontal plane is proportional to the ordinate at that section drawn from the line AB to the line $cdefk$ bounding the equilibrium-polygon; and the moments due to the vertical forces are proportional to the ordinates drawn to the line $rstv$, the numerical value being the length of the ordinate times 20 000, the pole-distance.

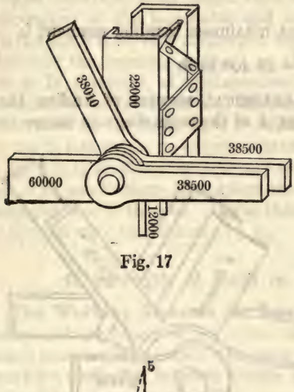

Fig. 17

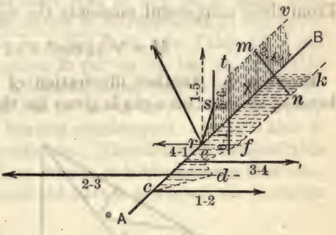

Fig. 18

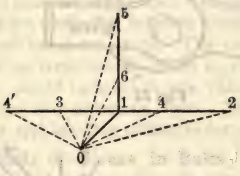

Fig. 19

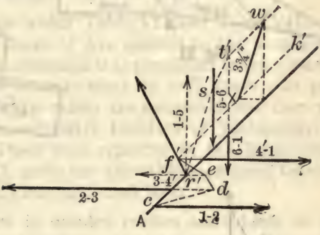

Fig. 20

Figs. 17 to 20. Pin-joint and Moment-diagrams

Where both moments are present, the resultant or true moment is proportional to the hypotenuse of the right-angled triangle having for its sides the ordinates in the two planes at the point in question. At X this is shown by the line mn. This measures 2.42 in, and being the longest diagonal or hypotenuse that can be drawn in the figure, it follows that the maximum bending moment on the pin is $2.42 \times 20\,000 = 48\,400$ in-lb.

To find the effect of changing the arrangement of the members on the pin, it may be assumed that the inclined bar is placed outside the inner chord-bar. The horizontal stress-diagram then becomes 1–2, 2–3, 3–4′, 4′–1. The equilibrium-polygons become $cdef'k'$ and $r's't'w$, as shown in Fig. 20. In these polygons the longest diagonal measures 3¾ in, which gives a bending moment of 3¾ in $\times$ 20 000 lb = 75 000 in-lb, showing that the arrangement of the eye-bars in Fig. 17 is better. As a rule the bending moment is less when those forces that

oppose each other are placed together. It may be further reduced by making the outside bar one-half the thickness of the main horizontal bars.

To check by the METHOD OF MOMENTS the value of the maximum bending moment obtained by the GRAPHIC METHOD for the first arrangement, the moments of the forces in the horizontal plane are taken about *r*. This gives

$$M_h = 38\,500 \text{ lb} \times 3.0 \text{ in} + 38\,500 \text{ lb} \times 1.0 \text{ in} - 60\,000 \text{ lb} \times 2.0 \text{ in}$$
$$= 34\,000 \text{ in-lb},$$

which is the value of the moment in the horizontal plane across the middle of the pin.

In the vertical plane moments are taken about a point *t*, giving

$$M_v = 34\,000 \text{ lb} \times 1.5 \text{ in} - 22\,000 \text{ lb} \times 0.75 \text{ in}$$
$$= 34\,500 \text{ in-lb}$$

From these component moments the resultant maximum bending moment is

$$M = \sqrt{34\,000^2 + 34\,500^2} = 48\,400 \text{ in-lb}$$

Example 7. Another illustration of the GRAPHICAL METHOD of finding the bending moment on a pin is given for the joint *A* of the truss-diagram shown in

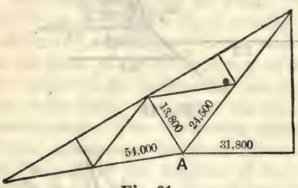

Fig. 21

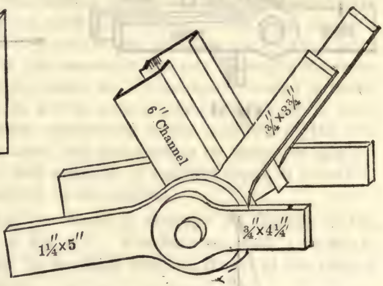

Fig. 22

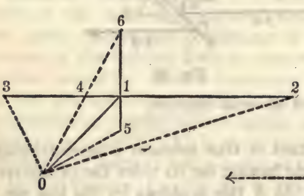

Fig. 23

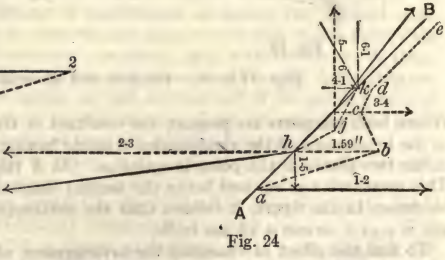

Fig. 24

Figs. 21 to 24. Force-polygons and Equilibrium-polygons for Bending Moments on a Pin

Fig. 21. Fig. 22 shows the arrangement and size of the members. The stresses given in Fig. 21 are for one-half the number of members at the joint. As in Example 6, the symmetrical arrangement makes it unnecessary to draw more

than one-half of the force-polygon and equilibrium-polygon. The web of the channel is reinforced to make it ⅝ in thick.

Solution. The line AB (Fig. 24) is drawn at an angle of 45° and *ah*, etc., are laid off to scale, equal to the distances between the members. At each point of application of a force a line is drawn parallel and to scale, to represent that force. The inclined forces are then resolved into their horizontal and vertical components. The force-diagram (Fig. 23) is then drawn, the horizontal forces being laid off to scale in the order in which they occur, 1–2, 2–3, 3–4 and 4–1. The pole-distance is then laid off at an angle of 45° and equal to 20 000 lb to the same scale of forces. The pole o is then joined with 2, 3, 4 and 1. Then in Fig. 24, *ab* is drawn parallel to o–2, *bc* to o–3, *cd* to o–4 and *de* to o–1. In the same way the line *hjkB* is drawn. From inspection it is seen that *hb* is the longest intercept, even longer than any diagonal that may be drawn from the extremities of the horizontal and vertical intercepts at any point along AB. To the same scale that makes o–1 represent 20 000 lb, *hb* represents 31 800 in-lb; therefore the bending moment on the pin is 31 800 in-lb. In Table VI a pin 2⅝ in in diameter, at a fiber-stress of 20 000 lb per sq in, has an allowable moment of 35 500 in-lb, and in Table V a bearing value on 1 in of 31 500 lb. A force of 31 800 lb on ¾ in is equal to 42 400 for a 1-in bar; so it is necessary to use a larger pin to accommodate the bearing requirement. From Table V a pin 3½ in in diameter is found to be necessary. The shearing value of this pin is 72 000 lb more than twice the load, so, again, it is the bearing that controls the size of the pin. If the thickness of the bars is increased the diameter of the pin may be reduced to 3 in.

4. Strength of Bolts in Wooden Trusses and Girders

The Working Stresses for Bolts on which Table VII and Table VIII are computed are based on a FACTOR OF SAFETY of five applied to the average of many tests on dry timber. In some specifications it is permitted to increase the BEARING PRESSURE between timber and bolts as much as 50% above that permitted for short struts. The values in the tables are somewhat less than the tests on large trusses made at the Massachusetts Institute of Technology, in 1897, would indicate as safe values. These were reported in the Engineering Record, November 17, 1900. Table IX gives the allowable maximum tension, shear and bending moments for wrought-iron and steel bolts.

Kinds of Stress in Bolts. BOLTS in wooden trusses are subject to the same kinds of stress as the RIVETS and PINS in steel structures. When the pieces joined are less than 2 in thick and the bolts are tightly drawn up so as to develop considerable frictional resistance between the pieces, the bolts are proportioned to resist the total force in SHEAR and in BEARING. When the pieces are more than 2 in thick the BENDING is taken into account and the bolts must be investigated for stresses in SHEAR, in BEARING and in BENDING. The SHEAR is assumed to be uniformly distributed over the cross-section of the bolt, and the BEARING AREA is the area of the projection of the bolt on the timber, which area is equal to the diameter of the bolt multiplied by the length in contact. The BEARING STRENGTH is given as a property of the bolt although its value depends upon the crushing strength of the timber. The BENDING MOMENT on the bolt is found in the same manner as for pins in steel trusses, although the cases are usually less complicated.

Illustrations of the Use of Bolts. The principles involved in the use of bolts in wooden trusses and girders and in the use of the tables may be best illustrated by the solution of examples in each of the following cases:

(1) Bolts in tie-beams, thin pieces.
(2) Bolts in girders to support brackets.
(3) Bolts as pins in the joints of trusses.
(4) Bolt-and-strap joints in trusses.
(5) Bolts under tension to hold the foot of a rafter.

(See, also, "Joints in Wooden Trusses," Chapter XXVIII, pages 1149 to 1160.

Case 1. Bolts in Tie-Beams, Thin Pieces. Tie-beams of wooden trusses, when longer than 30 ft, are usually made up of a number of pieces. This construction is cheaper than the use of a single stick. Two-inch planks bolted together are generally used. The location of the joints in the courses of planks and the number and size of the bolts are the special considerations in the design of such a joint. In general, the joints in adjacent courses are placed as far apart as possible and not more than two joints are placed opposite each other in the same section. The simplest case is that of a plain FISH-PLATE JOINT like a common BUTT-JOINT with two cover-plates as shown in Fig. 12. The number of BOLTS for such a joint is found in the same way as the number of RIVETS in steel tie-bars. The bolts must be spaced as required in the second column under each timber in Table VII, to provide against shearing in front of the bolt.

Table VII.* Safe Bearing Value of Bolts per Inch of Length Parallel to the Grain in Timber and Distance from Center to Center of Bolts or to End of Timber

Diameter of bolt, in	Long-leaf yellow pine		White pine and short-leaf yellow pine		Douglas fir		White oak	
	Bearing at 1 400 lb per sq in, lb	Distance, in	Bearing at 1 100 lb per sq in, lb	Distance, in	Bearing at 1 200 lb per sq in, lb	Distance, in	Bearing at 1 400 lb per sq in, lb	Distance, in
3/4	1 050	4 1/2	825	5 1/4	900	4 1/4	1 050	3 1/2
7/8	1 225	5	960	5 3/4	1 050	5	1 225	4
1	1 400	5 3/4	1 100	6 1/2	1 200	5 1/2	1 400	4 1/2
1 1/8	1 575	6 1/2	1 237	7 1/2	1 350	6 1/4	1 575	5
1 1/4	1 750	7	1 375	8	1 500	7	1 750	5 1/2
1 3/8	1 925	7 3/4	1 512	9	1 650	7 3/4	1 925	6 1/4
1 1/2	2 100	8 1/2	1 650	9 3/4	1 800	8 1/2	2 100	6 3/4
1 3/4	2 450	10	1 925	11 1/2	1 950	9 1/4	2 450	7 3/4
2	2 800	11 1/2	2 200	13	2 400	11 1/4	2 800	9
2 1/4	3 150	12 3/4	2 475	14 3/4	2 700	12 1/2	3 150	10
2 1/2	3 500	14 1/4	2 750	16 1/4	3 000	14	3 500	11 1/4
2 3/4	3 850	15 1/4	3 025	18	3 300	15 1/2	3 850	12 1/4
3	4 200	17	3 300	19	3 600	17	4 200	13 1/2

The distance from the end is equal to the diameter of the bolt plus the length on which twice the SHEAR is equal to the BEARING VALUE of the bolt against the end-fibers.

* When the effect of the inclined surfaces upon the unit stresses is taken into account, the formula for the normal intensity of stress for cylindrical pins or bolts, given in Chapter XXVIII, page 1138, may be used. This formula will give lower values than those of Table VII.

Table VIII.* Safe Bearing Value of Bolts per Inch of Length Across the Grain in Timber

Example 8. A typical tie-beam used as a lower chord of a Howe truss is shown in Fig. 25. It is 50 ft long, of Douglas fir and subject to the tension in the different panels shown in the figure.

Solution. The thickness of the plank is drawn out of scale in the figure to show the joints more clearly. The black circles show the vertical tension-rods, which so nearly cut the middle plank in two that it is not considered a part of the tensile member. The arrangement of the planks and the lengths to be used must be determined for each case. In the one shown there is but one splice in the middle panels where there is the greatest tension. The distance

XY is 12 ft, which is about as small as will serve for the transfer of the tension from A' to B. In this beam the two outer planks, A and A', must be large enough to resist the whole tensile stress in the middle panels because of the joints in B and C. At the inner end of the second panel there is 58 000 lb tension which must be carried to the end of the first panel. Because of the

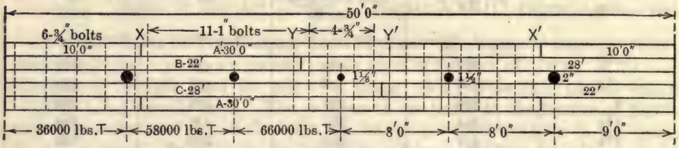

Fig. 25. Plan of Built-up Tie-beam

joints in A and A' this must be transmitted to B and C in order to pass the point X.

Assuming that 29 000 lb, one-half the tension, is carried on plank A to be transmitted to C by the shear and bearing on the bolts, and dividing this by 7 850 lb, the allowable shear on a 1-in bolt, four bolts are found to be necessary. But the bearing value of a 1-in bolt in Douglas fir 2 in thick, is only 2 400 lb, which makes twelve bolts necessary. These are required in the distance XY, 12 ft.

From the distances in Table VII, it is found that the end-bolts must be 5½ in from the ends of the planks, say 6 in; this leaves 11 ft, in which distance eight bolts are to be arranged. If four bolts are placed in pairs, two at each end, as

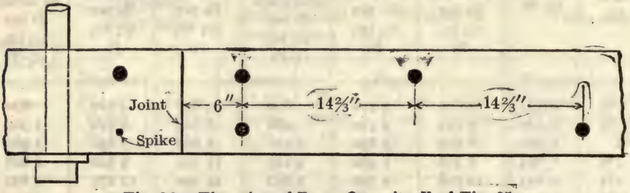

Fig. 26. Elevation of Beam Opposite X of Fig. 25

shown in Fig. 26, the intermediate spaces are 14⅔ in. The bolts bind the beam together better if they are staggered, as indicated in Fig. 26, and not placed on the middle line.

The number of bolts mentioned is sufficient to make the splice, but there should be bolts in the distance YY', and between the ends and X and X', to bind the planks together. These need not be as large or as close together as the others; ¾-in bolts spaced 2 ft are sufficient. There should be two bolts at the end of the beam. Each bolt should be driven through a hole of the same size as the bolt and the nuts should be screwed up tight.

Case II. Bolts in Girders to Support Brackets. The construction shown in Figs. 27 and 28 is commonly used in cases in which the requirements do not allow the girder to project its full depth below the joists. The BOLTS shown in Fig. 27 must be investigated for BEARING and SHEAR, and those shown in Fig. 28 for BEARING, SHEAR and BENDING. In either case the SHEARING VALUE of the bolt in single shear must equal or be greater than the greater of the forces S or S'.

The BEARING per inch on the wood of the girder, when B is in inches, is

$$(S + S')/B$$

This must be kept within the values given in Table VII for the timber used. For the case shown in Fig. 28 the BENDING MOMENT in pound-inches is

$$M = SL/2 \quad \text{or} \quad M = S'L/2$$

whichever is the larger. B and L are measured in inches and S in pounds.

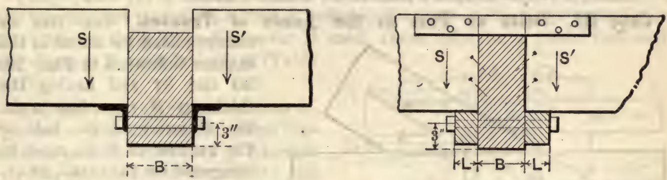

Fig. 27 Fig. 28

Figs. 27 and 28. Bolts Supporting Brackets on Girders

Example 9. For the construction shown in Fig. 27 it is required to determine the number and size of bolts, the Douglas fir girder being 8 by 14 in, with a span of 14 ft, and the Douglas fir joists 3 by 12 in, with a span of 20 ft, center to center of girders. The floor-load, including the floor, is 60 lb per sq ft. The angles are 4 by 3½ by ⅜ in.

Solution. The floor-area supported by the girder is 14 by 20 ft. At 60 lb per sq ft, the load is $14 \times 20 \times 60 = 16\,800$ lb. The load S, on one side, is 8 400 lb.

A ¾-in bolt has a shearing-value of 4 420 lb. Hence two bolts are necessary to satisfy the shearing condition. The bearing value of the bolt in the wood, across the grain, is, from Table VIII, 187 lb per inch of length, or 1 496 lb for the width of the girder. The number of bolts required, then, is 16 800 divided by 1 496 or approximately 11, which gives a spacing of about 15 in.

Example 10. In the construction shown in Fig. 28, the girder is 6 by 14 in, of Douglas fir and has a span of 12 ft. The joists are 2 by 12 in and have an 18-ft span, center to center of girders. The floor-load is 65 lb per sq ft. There are 3 by 4-in strips on the sides of the girder. The distance L is 3 in. It is required to find the number and size of bolts to be used.

Solution. The total load on the girder is

$$12 \times 18 \times 65 = 14\,040 \text{ lb}$$
$$S = 7\,020 \text{ lb}$$

The bearing load per inch of thickness of the girder is

$$\frac{14\,040}{6} = 2\,340 \text{ lb}$$

The bending moment on one side of the girder is

$$\frac{7\,020 \times 3}{2} = 10\,530 \text{ in-lb}$$

since the force S acts at the center of pressure on the bracket-strip, 1½ in from the edge of the girder.

The shear is 7 020 lb, which requires two ¾-in steel bolts at 4 420 lb for one as given in Table IX.

The bearing (Table VIII) on a ¾-in bolt is 187 lb per inch of length; therefore it requires thirteen bolts for bearing.

The allowable bending moment on a ¾-in steel bolt is 830 in-lb, from Table IX. To take care of the 10 530 in-lb requires thirteen bolts. A ⅞-in steel bolt has an allowable bending moment of 1 310 lb-in, making eight of them sufficient. The 3 by 4-in pieces may be held in place by thirteen ¾-in bolts spaced 11 in on centers, if two of them are placed 6 in from the ends.

Case III. Bolts as Pins in the Joints of Trusses. For TIES or STRUTS joined by BOLTS in the manner indicated in Figs. 29, 30 and 31 and having the thickness B exceeding 2 in, the diameter of the bolt or the number of bolts must be computed for SHEARING, BEARING and FLEXURE.

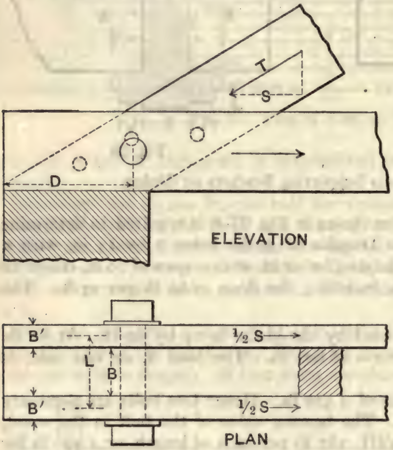

Fig. 29. Bolt through Rafter and Tie-beam

For any of these joints the forces are as follows:

The single shear $= S/2$

On the sections between B and B' (Fig. 30)

The bearing on the pin per inch of length $= S/B$ or S'/B'

The greater is to be used.

The bending moment $= SL/12$

on the assumption of a CONTINUOUS BEAM, uniformly loaded.

If there are more bolts than one, the quantities obtained by the above formulas are to be divided by the number of bolts to find the part to be taken care of by one bolt.

In Fig. 29, S is the horizontal component of the thrust T.

Example 11. It is required to determine the diameter of a bolt for a joint like that shown in Fig. 29. The rafter is 6 by 10 in, of Douglas fir; the tie-beams 3 by 10 in, of the same material, the thrust in the rafter 30 000 lb, and its inclination 30°.

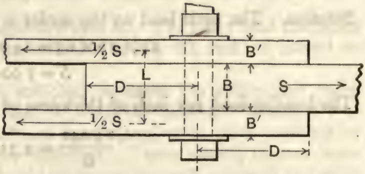

Fig. 30. Bolt in Wooden Tie-beam

Solution. The horizontal component of 30 000 lb at 30° is practically 26 000 lb. Then $S = 26\ 000$ lb and the shear $= 13\ 000$ lb. $B = 6$ in and $L = 9$ in.

$$\text{Bearing per inch of length on the bolt} = 26\ 000/6 = 4\ 333 \text{ lb}$$
$$\text{Bending moment} = 26\ 000 \times 9/12 = 19\ 500 \text{ in-lb}$$

In Table IX, a 1⅜-in steel bolt is found to be necessary to resist a shear of 13 000 lb, and a 2¼-in bolt for a bending moment of 19 500 in-lb. To resist 4 333 lb end-bearing pressure on 1 in a larger bolt is required than is given in Table VII. Dividing 4 333 by 1 200, the allowable bearing on Douglas fir, a 3⅝-in bolt is found to be necessary. This is larger than it is desirable to use, so the joint must be redesigned with a view to reduce the bearing pressure on

the bolt. If an 8 by 8-in strut and 4 by 8-in tie-beams are used, B becomes 8 in and L 12 in. This gives

Bearing pressure = 26 000/8 = 3 250 lb per inch of length of the bolt
Bending moment = 26 000 × 12/12 = 26 000 in-lb

The total shear at the section on one side of the strut is the same as before.

From Table VII it is found that a 2¾-in bolt is large enough to provide for the bearing and that a 2½-in bolt is sufficient for the bending as given in Table IX. Hence if an 8 by 8-in strut is used, there must be a 2¾-in bolt and the distance D must be 15½ in (Table VII).

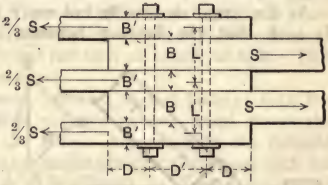

Fig. 31. Bolts in Wooden Tie-beam

Example 12. For the same construction as in Fig. 29 and the same conditions as in the first part of Example 11, it is required to determine the size of the bolts when it is necessary to use three.

Solution. The shear, bearing, and bending moment are the same as in Example 11, but because there are three bolts each quantity is divided by 3 to determine the force resisted by each.

Shear = 13 000/3 = 4 333 lb and requires a ¾-in steel bolt (Table IX)
Bearing = 4 333/3 = 1 444 lb and requires a 1¼-in bolt (Table VII)
Bending moment = 19 500/3 = 6 500 in-lb, and requires a 1½-in steel bolt (Table IX).

In this case the bending moment determines the size of the bolts, which may be arranged as shown by the dotted circles in Fig. 29.

Example 13. It is required to determine the diameter of the bolt for the construction shown in Fig. 30, in which the inner beam is of Douglas fir and 6 by 8 in in section, and the outer beams 3 by 8 in, the tension being 24 000 lb.

Solution. $S = 24\,000$; $B = 6$ in; $L = 9$ in.

Single shear on the bolt = 24 000/2 = 12 000 lb
Bearing-pressure per inch of length of bolt = 24 000/6 = 4 000 lb
Bending moment = 24 000 × 9/12 = 18 000 in-lb

From Table IX a 1¼-in steel bolt is found sufficient to resist the shear, and a 2¼-in bolt large enough to resist the bending. In Table VII the largest bolt considered, 3 in, is too small in bearing value. Dividing the load to be resisted by 1 200 gives 3⅓ in, as the diameter necessary to resist the bearing. The distance D must be 4 000/(2 × 130) + 3⅓ in or 18¾ in.

Example 14. If two bolts are used, one behind the other, it is required to determine the diameter of the bolt that should be used, the conditions and loading being the same as in Example 13.

Solution. Dividing the quantities obtained in Example 13 by 2,

Single shear = 6 000 lb and requires a ⅞-in steel bolt
Bearing = 2 000 lb and requires a 2-in bolt
Bending moment = 9 000 in-lb and requires a 1¾-in steel bolt

The allowable bearing on a 1¾-in bolt is (2½ %) less than the required amount, so that in general, since the other requirements are more than satisfied, the smaller bolt would be used. For the 1¾-in bolt, the distance D is 9¼ in. The space between the bolts may be increased somewhat beyond the value given in

Table VII, and they may be located out of the same line as a further precaution against splitting.

Case IV. Bolt-and-Strap Joints in Trusses. The construction shown in Fig. 32 is sometimes used to connect the foot of the rafter of a wooden truss to the tie-beam. When the distance D is sufficient to resist the shear due to the thrust of the rafter, the strap is of value only in holding the rafter in place, and there are no greater pressures brought upon the BOLT. When it is impossible to make D the necessary length, the BOLT and STRAP must be designed to resist the full force in the direction of the STRAP.

As the STRAP is usually not more than from ½ to ¾ in thick, its width is such that the bearing between it and the rafter is small compared with that between the BOLT and rafter. The forces acting on the BOLT are the only ones that need consideration. These are:

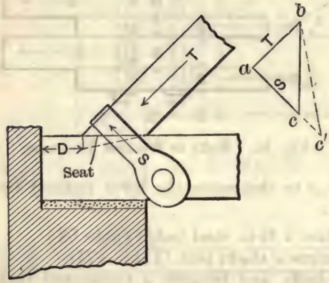

Fig. 32. Strap and Bolt at Foot of Rafter

SINGLE SHEAR = $S/2$ = the tension in the strap on one side

BEARING PRESSURE per inch of length = S/B, where B is the width of the tie-beam in inches

BEARING PRESSURE per inch of length between strap and bolt = $S/2\,t$

To find the value of S, the force-polygon is drawn as shown at the right in Fig. 32. T is drawn parallel to the rafter and with a length, to a convenient scale, equal to the thrust. From the end a an indefinite line is drawn parallel to the axis of the strap, and from b another line perpendicular to the SEAT of the rafter. These intersect at c, so that ac, measured by the same scale used in laying off T, is the magnitude of the force S in the strap. If the rafter rests on top of the beam, bc is vertical, but if the tie-beam is dapped, as shown by the dotted line, the line from b is drawn perpendicular to the bottom of the notch, making the intersection at c'. It is seen that notching the tie-beam in this way increases the stress in the strap.

Example 15. It is required to determine the size of a strap and pin-bolt to hold the rafter without notching into the tie-beam of a long-leaf yellow-pine king-post truss. The rafter is 6 by 6 in, is inclined at an angle of 45° and is under a compressive stress of 18 000 lb. The tie-beam is 6 by 8 in in section.

Solution. Since the inclination is 45°, a consideration of the force-polygon in Fig. 32 shows ab equal to ac, so that

The force S = the thrust T = 18 000 lb
Single shear on bolt = 18 000/2 = 9 000 lb
Tension in strap on one side = 9 000 lb
Bearing pressure per inch of bolt against wood = 18 000/6 = 3 000 lb
Bearing pressure in pounds per inch between strap and bolt = 9 000/t
in which t equals the thickness of the strap.

The allowable pressure between the strap and the top of the rafter is 350 lb per sq in (Table VII), which, on the 6-in rafter, gives

Allowable load per inch of width of strap = 6 × 350 = 2 100 lb

The strap then must be 18 000/2 100 or 8.6 in wide. At 10 000 per sq in in tension the necessary section of the strap is 0.9 sq in, requiring a thickness of

about 0.1 in, a sufficient thickness if the strap were strong enough to develop a uniform pressure over the rafter. It is not good practice, however, to use such thin material, because of the danger of loss of strength due to corrosion. No metal less than 3/8 in thick should be used in such places.

The bearing-pressure per inch, between the strap and the bolt, for a 3/8-in strap = 9 000/3/8 = 24 000 lb

The bolt, then, must take a single shear of 9 000 lb, a bearing pressure of 3 000 lb against the wood for each inch of length, and a bearing of 24 000 lb per inch of length against the strap. From Table IX a 1 1/8-in steel bolt is sufficient to resist the shear, from Table V a 2-in bolt is large enough to resist the bearing from the strap, and from Table VII a 2 1/4-in bolt is found necessary to resist the 3 000-lb bearing from the wood per inch of length of bolt. This makes the 2 1/4-in bolt satisfactory for the joint.

The pressure from the bolt to the wood, however, is not parallel with the grain but inclined at 45°. The allowable pressure against wood across the grain is about one-fourth of that with the grain. According to the formula given in Chapter XXVIII, page 1138, the allowable pressure per square inch for this case is 612 lb instead of the 1 400 per sq in allowed for direct compression with the grain. The reduced allowable pressure makes it necessary to use a 4.9-in bolt, say a 5-in bolt, which would be impracticable, for it would almost cut the tie-beam in two. It thus appears that this form of joint is not good design for a truss of this span. For shorter spans the joint may be made in accordance with the requirements given. It has the advantage of not presenting any projections below the tie-beam.

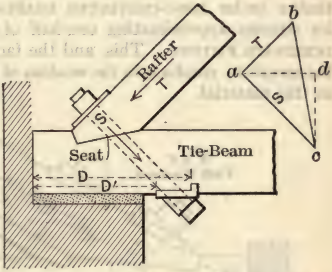

Fig. 33. Bolt in Tension at Foot of Rafter

Case V. Bolts in Tension to Hold the Foot of a Rafter. In the joint shown in Fig. 33 the bolt is subject to DIRECT TENSION only. The amount of the tension S is found by the construction explained in Case IV. The rafter may be let into the tie-beam or rest on top of it, the tension in the bolt being less in the latter case; but it is easier to erect the truss if the rafter is NOTCHED INTO THE BEAM from 1 1/4 to 1 1/2 in for ordinary spans and loads, to hold it while the pieces are fitted. After this is done, the holes may be bored exactly where required.

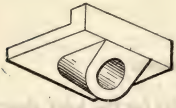

Fig. 34. Special Washer

Whenever S exceeds about 10 000 lb for trusses made of timber for which the highest bearing stresses are allowed, a CAST PLATE, as shown in Fig. 34 and made to fit the inclination of the bolt, should be let into the tie-beam at the head of the bolt to distribute the pressure. The diameter of the hole for the bolt should be 1/8 in larger than the diameter of the bolt. The distance D must be made sufficient to provide for the horizontal component of S, at the allowed working stress of the material for shear with the grain.

The horizontal component is found by drawing a vertical line from c and a horizontal line from a and measuring ad to the scale of the diagram. For safety, this force must be less than the product of the distance D, the width of the beam and the allowed shearing-stress given in Table I, page 412.

Example 16. For the same conditions as in Example 15, for the size of the members and the thrust in the rafter, it is required to determine the diameter of the bolt and the distance D for a joint of the type shown in Fig. 33.

Solution. To find S, draw T equal to 18 000 lb, at a convenient scale, and parallel to the rafter. At a, draw an indefinite line perpendicular to the rafters and at b a line perpendicular to THE SEAT of the rafter. This makes S greater than in Example 15, as ac now scales 27 000 lb. From Table IX, a 1¾-in steel bolt is sufficient to take this in direct tension. The horizontal component found as directed above, scales 19 000 lb. The width of the tie-beam is 6 in, which at the allowed shearing-stress, 150 lb per sq in, gives 900 lb as the stress that must be cared for by each inch of D. 19 000 lb divided by 900 gives 21 in, the required distance D. (See, also, Chapter XXVIII, Joints in Wooden Trusses.)

The compression against the grain on the end of the cast-iron washer must also be investigated. 19 000 lb divided by the width, 6 in, gives 3 166 lb that must be resisted per inch of width of beam. At 1 400 lb per sq in, as an allowable working stress, this makes it necessary to set the casting 2¼ in into the lower side of the beam, which exceeds the depth usual in ordinary practice. Some tests made at the Massachusetts Institute of Technology on large trusses, and reported in 1897, indicated that for a TEST CARRIED TO RUPTURE the stresses prescribed for usual designs might safely be more than doubled. Tests on timber under LONG-CONTINUED LOADING indicate that rupture finally occurs for stresses approximating one-half of those developed in TESTS CARRIED TO IMMEDIATE FAILURE. This, and the fact that decay may affect the strength of the members, emphasizes the wisdom of using CONSERVATIVE WORKING-STRESSES in this material.

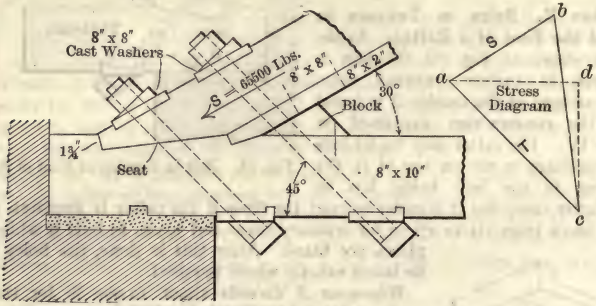

Fig. 35. Joint with Two Bolts in Direct Tension

Example 17. It is required to determine the size of bolts for the joint shown in Fig. 35, the thrust being 65 500 lb and the truss-members being made of long-leaf yellow pine.

Solution. The tension in the bolts is found first by drawing the force-polygon as shown at the right in the figure. To the same scale that ab represents 65 500, ac represents 96 500 lb. If the load is equally divided between the bolts, each has a tension of 48 250 lb. From Table IX this force requires a 2¼-in steel bolt.

The horizontal component ad is 68 350 lb, which must be resisted by the shearing strength of the wood between the end of the cast-iron washer on the under

side of the tie-beam and the end of the beam resting on the wall. At 150 lb per sq in, this requires 68 350/150, or 455 sq in. If the beam is 8 in wide, this requires a length of 57 in along the beam from the washer to the end.

The bearing of the cast-iron washer against the end-fibers of the tie-beam is also 68 250 lb. At an allowable pressure of 1 400 lb per sq in the depth of the washer should be $68\,350/(8 \times 1\,400) = 6.1$ in. This would almost cut the beam in two. The ultimate strength of the wood in compression is about five times the working stress, and since a considerable part of the horizontal force may be resisted by the body of the bolt as well as by the friction of the washer, it is probable that with washers ¾ in thick there would be little sign of weakness at the joint even when the truss is fully loaded.

Theoretically the washers on the top surface of the rafter should be determined by the allowable working stress in compression across the fibers. This for long-leaf pine is taken at 350 lb per sq in (Table VI, page 454). The area, then, is 48 250/350, or 138 sq in. This requires a washer 11¾ in square. The 8 by 8-in washer used, assumes a pressure of 755 lb per sq in, but as the tests of the Forest Service of the United States Department of Agriculture give 3 480 lb per sq in as the elastic limit for long-leaf yellow pine, it is very likely that there would be no signs of injury at this point, other than a SLIGHT INDENTATION, when the truss is fully loaded.

CHAPTER XIII

BEARING-PLATES AND BASES FOR COLUMNS, BEAMS AND GIRDERS. BRACKETS ON CAST-IRON COLUMNS*

By
HERMAN CLAUDE BERRY
PROFESSOR OF MATERIALS OF CONSTRUCTION, UNIVERSITY OF PENNSYLVANIA

1. Bearing-Plates and Bases

The Purpose of Bearing-Plates or Bases. When a heavily loaded column, beam or girder is supported on a masonry wall or pier, a BEARING-PLATE or BASE of suitable dimensions must be used to distribute the load so that the pressure will not exceed the safe BEARING STRENGTH of the masonry (Table I).

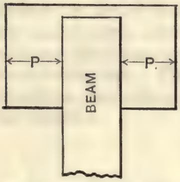

Fig. 1. Simple Bearing-plate

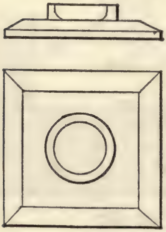

Fig. 2. Beveled Cast-iron Plate with Pin

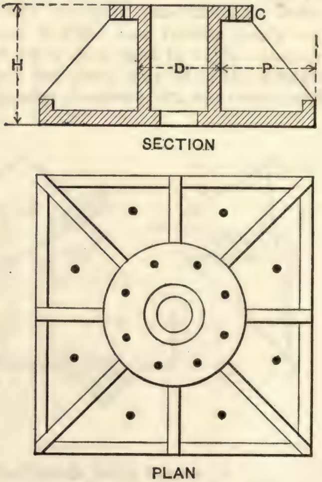

Fig. 3. Ribbed Cast-iron Plate

The BEARING-PLATE is designed to be stiff enough to distribute the pressure under it uniformly, and its area is determined by dividing the load on it by the allowable pressure per unit of area (Table II).

Simple Bearing-Plates. Fig. 1 shows a SIMPLE BEARING-PLATE under a beam. It may be a steel or cast-iron rectangular plate of sufficient thickness to prevent its bending at the edge of the beam from the pressure of the

* See, also, Chapter XIV, Subdivisions 8 to 11.

masonry below. For anchors for steel beams on bearing-plates, see Chapter XV, page 619.

Cast-Iron Plates with Pin. Fig. 2 is a cast-iron PLATE WITH A DOWEL-PIN to fit inside the shell of a cast-iron column, or into a recess cut in the bottom of a wooden one. The pin holds the base-plate in position.

Cast-Iron Ribbed Bases. Fig. 3 is a cast-iron RIBBED BASE for a large cylindrical cast-iron column, capable of supporting a load heavy enough to break a plate similar to the one shown in Fig. 2, at the edges of the column, unless the plate were made unduly thick.

Table I. Allowable Bearing Pressure on Different Kinds of Masonry

Kind of masonry	Allowable pressures	
	Lb per sq in	Tons per sq ft
From the building laws of New York, 1916		
Brick, in lime mortar	112	8
in lime-and-cement mortar	162	11½
in Portland-cement mortar	250	15
Rubble masonry, in Portland-cement mortar	140	10
Concrete, Portland cement, 1 : 2 : 4	500	36
Recommended by a committee of Chicago architects and engineers in 1908		
Rubble, in lime mortar	60	4.32
in Portland-cement mortar	100	7.2
Coursed rubble, in lime mortar	120	8.6
in Portland-cement mortar	200	14.4
Ashlar, limestone, in Portland-cement mortar	400	28.8
granite, in Portland-cement mortar	600	43.2
Concrete, Portland-cement, 1 : 2 : 4, hand-mixed	350	25.2
machine-mixed	400	28.8

The Bases of the Steel Cores of Composite Columns used in reinforced-concrete construction have areas sufficient to distribute the loads of the columns over the concrete in the footings at the allowable working stress of the concrete, which is usually 500 lb per sq in. (See, also, page 474, Figs. 14 and 15.)

Example 1. The basement-columns of a warehouse are designed for a load of 212 000 lb each. It is required to determine the size of the base-plates to rest on the concrete foundations.

Solution. At an allowable pressure of 208 lb per sq in, the required area is 212 000/208 or 1 020 sq in, or about 32½ in square. The plan and section of the base-plate is shown in Fig. 3.

Forms of Base-Plates. For small columns and wooden posts with light loads, PLAIN FLAT PLATES of cast iron or steel are generally used. The cast-iron plates may have a raised ring or cross to fit inside a hollow metal column, or a dowel, from 1½ to 2 in in height for a wooden one. If the plate is very thick the outer edges may be beveled to save weight, as shown in Fig. 2, but no part of it should be less than about ¾ in thick.

Table II. Allowable Loads on Standard, Steel Bearing-Plates on Walls

Bearing on wall, in	Size of plate, in	Safe bearing value of plate in pounds		
		Bricks laid in mortar of		
		Lime, 112 lb per sq in	Lime and cement, 162 lb per sq in	Cement, 208 lb per sq in
6	6×6	4 070	5 800	7 500
	6×8	5 400	7 800	10 000
	6×10	6 700	9 700	12 500
8	8×8	7 200	10 200	13 300
	8×10	9 000	12 100	16 600
	8×12	10 700	15 500	20 000
10	10×10	11 200	16 200	20 800
	10×12	13 450	19 500	25 200
	10×14	15 700	22 700	27 900
12	12×12	16 150	23 300	30 000
	12×14	18 800	27 400	35 000
	12×16	22 000	31 200	40 100
	12×18	24 200	34 500	45 000
14	14×14	22 100	31 800	40 800
	14×16	25 000	36 300	46 600
	14×18	28 200	40 800	52 400
	14×20	31 400	45 400	58 200
16	16×16	28 700	41 500	53 200
	16×18	32 300	46 600	59 800
	16×20	35 800	51 900	66 700
	16×22	39 500	57 000	73 200

The last column applies to concrete walls also.

Ribbed Bases. If the calculated size of a bearing-plate is so large that its projection beyond the edge of the column would be more than about 6 in, a RIBBED BASE similar to that shown (Fig. 3) for a cylindrical column is used. For such bases it is unnecessary to consider the transverse stresses. When these bases are bolted to the columns they add greatly to the general stability of the supporting members because of the greater width of such bases.

Proportions of Ribbed Bases. The HEIGHT H of this type of base should be approximately equal to the PROJECTION P, and the DIAMETER D equal to the diameter of the column. The projection C should be at least 3 in to permit the bolting of the column to the base. The THICKNESS of all parts of the casting should be the same and approximately equal to the thickness of the column-shell. There must be no thin webs as they result in breakage from shrinkage-stresses.

Base-Plates for Steel Columns are usually made of STEEL PLATES and SHAPES as shown on the channel-columns in Chapter XIV, Figs. 17, 18 and 19. Cast-iron bases are sometimes used for very heavy columns. If conditions are favorable to the action of corrosion the cast iron is to be preferred.

The Area of Bearing-Plates under Beams and Girders is found in the same manner as the area of plates under columns. If the load on the beam is uniformly distributed over the beam or concentrated at its middle, the required area of the plate is one-half the total load on the beam divided by the allowable bearing per unit of area on the masonry; but if the load is a moving load, the greatest possible end-reaction must be divided by the allowable bearing. For example, a heavily loaded truck standing near the end of the beam causes a pressure on the bearing-plate much greater than one-half its weight. The true reaction for the actual conditions must be found by the methods explained in Chapter IX.

The Thickness of the Bearing-Plate is found by the formula used to determine the flexure of beams. It must be determined in each case. For a typical case the forces acting are shown in Fig. 5, which represents a transverse

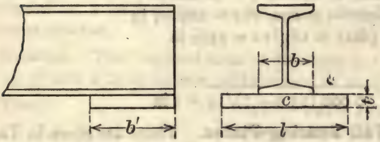

Fig. 4. Simple Bearing-plate under I Beam

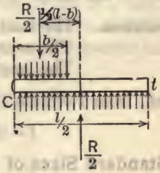

Fig. 5. Forces Acting on Half of Bearing-plate

vertical section through one-half the plate. The vertical section at C, and through and parallel with the web of the **I** beam, is taken through the center of the plate, which is the dangerous section, or section of maximum bending moment.

In Figs. 4 and 5, b' is the bearing depth on the wall;
l is the length of the plate, parallel with the wall;
b is the width of the flange of the beam;
R is the load on the bearing-plate.

Replacing the uniform loads by the equivalent forces at the center of gravity of each, these forces are represented by the longer arrows. The bending moment at the section at c is the same as the moment of the concentrated forces, giving,

$$M = (R/2 \times l/4) - (R/2 \times b/4)$$

or

$$M = R/2 \times (l - b)/4$$

This is equal to the resisting moment at the same section c, or, at stress S, SI/c, in which I/c is the section-factor. (See Chapter XV.) This reduces to $St^2b'/6$. Equating the bending moment and the resisting moment there results

$$St^2b'/6 = R(l - b)/8$$

and

$$t = 0.866\sqrt{R(l - b)/Sb'}$$

For $S = 3\,000$ for cast iron, this reduces to

$$t = 0.0158\sqrt{R(l - b)/b'} \qquad (1)$$

For $S = 16\,000$ for steel plates, it becomes

$$t = 0.00685\sqrt{R(l - b)/b'} \qquad (2)$$

Example 2. It is required to determine the length and thickness of a cast-iron bearing-plate under a wooden beam which is 10 in wide and supports a load of 24 000 lb. The plate is 8 in wide and bears that width on a brick wall laid up in lime mortar.

Solution. The load on the plate is 24 000/2 = 12 000 lb. From Table I, the area of the plate is 12 000/112 = 108 sq in. Hence, if the width of the plate is 8 in, its length must be 13½ in. Then, from Formula (1)

$$t = 0.0158\sqrt{12\,000\,(13\tfrac{1}{2} - 10)/8} = 1.15 \text{ in}$$

A plate 1¼ in thick would be used.

Example 3. It is required to determine the length and thickness of a steel bearing-plate under the end of a 24-in 80-lb **I** beam supported on a 12-in brick wall laid up in lime-and-cement mortar and carrying a load of 60 000 lb. The width of the flange of the beam is 7 in.

Solution. The load on the plate is 60 000/2 = 30 000 lb
The area of the plate = 30 000/162 = 185 sq in
The length of the plate is 185/12 = 15½ in

Then, from Formula (2)

$$t = 0.00685\sqrt{30\,000\,(15.5 - 7)/12} = 1 \text{ in}$$

Standard Sizes of Steel, Wall Bearing-Plates. These are given in Table II, and are based upon ALLOWABLE PRESSURES of 112, 162 and 208 lb per sq in. These UNIT PRESSURES are based upon the ALLOWABLE PRESSURES of the New York and Philadelphia building laws which are expressed in tons per square foot. Because of the complicated formula on which the thickness depends it is best to compute the thickness for each case.

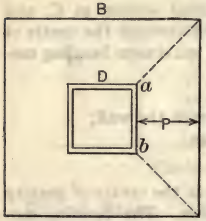

Fig. 6. Flat Bearing-plate for Column

Bearing-Plates under Columns. The general rules already given for the proportions of RIBBED BASES similar to that shown in Fig. 3 are a sufficient guide for detailing such bases; but in case simple FLAT PLATES are used under columns, their thickness must be computed according to the principles governing bending. The stress in a FLAT PLATE supported at the middle and subjected to a uniform load cannot be determined by the ordinary methods of mechanics. The approximate solution here given is generally used in the design of BASE-PLATES and COLUMN-FOOTINGS. It gives values found to be safe in practice.

In Fig. 6, let B = the length of the side of the plate as determined by the allowable pressure on the supporting masonry;
D = the side or diameter of the column;
$P = (B - D)/2$ = the projection of the plate;
t = the thickness of the plate;
A' = the area of the plate outside the column;
w = the allowable bearing pressure on the masonry due to the load on the column.

Then in Fig. 6, the pressure on one-fourth of A', shown enclosed by the dotted lines in the figure, causes shearing and bending stresses in the section of the plate along the line ab. Considering the part enclosed and taking moments about the section ab, the following equation is obtained from the usual bend-

ing-moment formula. (See Chapter XV, page 557.) That is, the resisting moment equals the bending moment, or

$$SI/c = \tfrac{1}{4} A'Pw$$

For the rectangular section at *ab*, this may be written

$$St^2D/6 = \tfrac{1}{4}A'Pw$$

whence

$$t = \sqrt{3\,A'Pw/2\,SD}$$

which becomes for $S = 3\,000$

$$t = 0.0224\sqrt{A'Pw/D}$$

and for

$$S = 16\,000$$

$$t = 0.0097\sqrt{A'Pw/D}$$

Example 4. It is required to determine the size and thickness of a cast-iron bearing-plate to be used under a wooden post 12 in square in cross-section and designed for a load of 115 200 lb. The plate is to be set on brickwork laid in cement mortar.

Solution. The required area of the base is 115 200/208 = 565 sq in. $\sqrt{565} = 23.76$ and a 24-in square plate would be used.

Then

$$A' = 576 - 144 = 432 \text{ sq in}$$
$$P = (24 - 12)/2 = 6 \text{ in}$$
$$D = 12 \text{ in}$$
$$w = 208 \text{ lb per sq in}$$

Hence

$$t = 0.0224\sqrt{432 \times 6 \times 208/12} = 4.75 \text{ in}$$

This thickness may be beveled to 1½ in at the edge. The computed thickness is greater than is usual for such plates, some formulas having more practical constants which really assume a stress of about 10 000 lb per sq in in cast iron in bending.

If the plate is made of steel

$$t = 0.0097\sqrt{432 \times 6 \times 208/12} = 2 \text{ in}$$

2. Bearing-Brackets on Cast-Iron Columns

The Usual Column-Connections for fastening beams and girders to cast-iron columns are shown in Fig. 7.* The end of the beam or girder is set on a SHELF *P*, under which is a BRACKET-SUPPORT *C*, cast on the side of the column. For a single beam, one bracket is sufficient; for wide beams or girders there should be two ribs. The ends of the beams are fastened to the column by bolting to LUGS *L*, cast on the column above the bracket. Sometimes a column is fastened by bolts passing through the bottom flange of the beam and through the shelf-plate. This connection greatly decreases the lateral stability of a building and should not be used.

The Shelf and Brackets, when loaded, are subject to SHEARING and BENDING-STRESSES. The SHEAR at the outer surface of the column-shell is equal to the end-reaction of the beam it supports. The BENDING-STRESS is due to the application of the load on the shelf-plate at some distance from the surface of the column. It causes a tension at the top of the bracket which tends to tear out the shell of the column, and causes, also, a compression at the foot of the rib. The THICKNESS OF THE RIB must be great enough to withstand the compression from the load above; and since the stress is variable along a section,

* See also, Figs. 5 and 7, pages 457 and 458.

as along the line X, a rough approximation may be made by assuming the stress at the extreme edge to be twice the average stress, and by further assuming that the section in the rib takes care of all the compression. This makes it unnecessary to find the CENTER OF GRAVITY and the MOMENT OF INERTIA of the section at X, both of which must be known if the FLEXURE-FORMULA is used. This procedure, also, makes unnecessary any assumption as to the true position of the CENTER OF PRESSURE on the top surface of the bracket. With the thickness of rib given in the tables there is an ample FACTOR OF SAFETY for any load

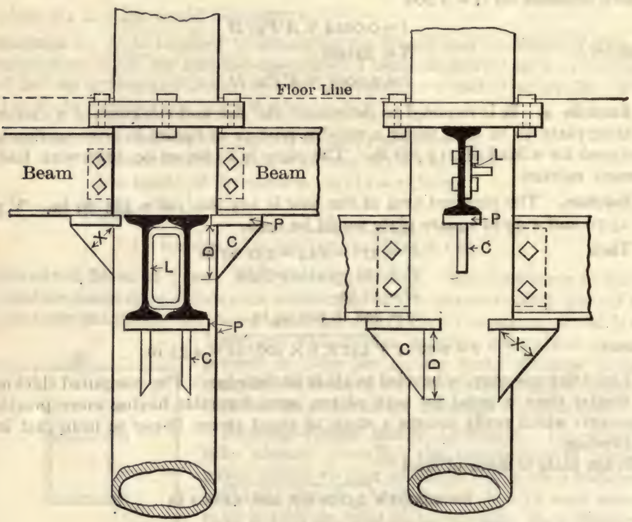

Fig. 7. Cast-iron Columns with Bearing-brackets

that may be applied through a beam. The double ribs are required when wide beams are used, not for strength, but to prevent the failure of the shelf from ECCENTRIC LOADING.

Tests of Cast-Iron Brackets. Brackets of cast-iron columns tested by the New York Building Department gave a SHEARING STRENGTH of 4 200 lb per sq in on the section at the column when the load was applied at the end of the bracket, and an average of 8 000 lb per sq in when the load was distributed over the bracket-shelf. The RANGE OF STRESS in the first case was from 2 450 to 5 600 and in the second from 4 100 to 10 900 lb per sq in. In seventeen out of twenty-two tests the MANNER OF FAILURE was the tearing out of a hole in the body of the column. It appears that when the thickness of the rib and shelf is the same as that of the shell of the column, there is generally ample strength for the support of beams and girders; but that in the case of very heavily loaded beams, the SHEARING and CRUSHING STRENGTH should be investigated. From the results of the tests mentioned, a low WORKING STRESS FOR SHEAR must be assumed.

The Bevel of Brackets. If the shelf P (Fig. 7), on which the beam rests, is cast SQUARE with the column, when the beam deflects, the load is brought on the extreme end of the bracket, causing an increased bending-stress in the

bracket and connections and tending to tear a hole in the column-shell. To avoid this the bracket-shelf should be sloped downward, away from the column, and should have a BEVEL of ⅛ in to the foot.

Standard Connections for Cast-Iron Columns. Table III, published originally in the Passiac Rolling Mill Handbook, and widely used by other manufacturers, will be found useful when detailing cast-iron columns.

CHAPTER XIV

STRENGTH OF COLUMNS, POSTS AND STRUTS

By

CHARLES P. WARREN

ASSISTANT PROFESSOR OF ARCHITECTURE, COLUMBIA UNIVERSITY

1. General Principles and Definitions

Slenderness-Ratio. The manner in which a material fails under compression or pressure depends not only upon its nature, but also upon its dimensions and form, that is, upon the ratio of its length to its cross-section or diameter. This ratio is denoted by l/r and is known as the SLENDERNESS-RATIO.

Three Classes of Columns. The actual compressive strength of a material must be determined on very short specimens in which there is no tendency to bend or to buckle. The load required to break the specimen does not change much until the length is increased to about TEN TIMES THE DIAMETER OR LEAST LATERAL DIMENSION. When that ratio is exceeded, the specimen tends to fail by BENDING or by BUCKLING instead of by direct compression. According to their manner of failure, therefore, columns in general may be divided into three classes:

(1) SHORT COLUMNS, in which the slenderness-ratio does not exceed 10 and which fail by direct compression.

(2) COLUMNS in which the slenderness-ratio varies from 10 to 30 for timber and cast iron and from 10 to 90 for steel. The failure of columns of this class is due partly to direct compression and partly to bending.

(3) LONG COLUMNS, in which the slenderness-ratio exceeds 30 for timber and cast iron and 90 for steel. These columns fail wholly by bending or buckling, which causes flexural stresses of compression and tension on the concave and convex sides respectively.

2. Strength of Short Wooden Columns

The Safe Load for a Short Wooden Column, the length of which is not more than 10 times the least dimension, may be computed by the formula

$$\text{Safe load} = \frac{\text{area of cross-section} \times S}{\text{factor of safety}} \qquad (1)$$

in which S denotes the crushing strength of the given material as stated in Table I.

The Factor of Safety to be selected depends upon the place where the column is used, the load which comes upon it, the quality of the material and, in a large measure, upon the value given to S. For lumber of ordinary quality, containing no very bad knots, a FACTOR OF SAFETY of five may be used; or, in other words, the safe stress per square inch of section-area may be taken as one-fifth of the values given in Table I. If the column is badly season-checked, cross-grained, or contains bad knots, a larger factor, say six or seven, should be used. The character of the load, also, should be taken into consideration in determining the factor of safety. Thus for a wooden post supporting a brick wall a larger factor should be used than for one supporting a floor, as in the former case the full load is at all times on the post, and the least reduction of its section-area in

case of fire might cause it to give way. Wooden posts supporting machinery, or wooden struts in railway bridges, should have a factor of safety of from six to eight, if the values of S given in Table I are used.

Table I.* Average Crushing-Loads in Pounds per Square Inch, for Building Materials

Materials	Crushing-loads, lb per sq in	Materials	Crushing-loads, lb per sq in
	S		S
For stone, brick, concrete and masonry, see Chapter V		Woods (continued)	
		Cypress	3 500
		Hemlock	4 000
Metals		Oak, white	5 000
		Pine, long-leaf yellow	5 000
Cast iron	80 000	Pine, short-leaf yellow	4 000
Wrought iron	55 000	Douglas fir	4 500
Steel, rolled shapes	60 000	Pine, Norway	3 500
		Pine, white	4 000
Woods, with the grain†		Redwood, California	4 000
Cedar	3 500	Spruce	4 500
Chestnut	4 000	Whitewood	3 000

* See, also, Table XVI, page 647, and Table I, page 1138.

† These are values for wooden columns under 15 diameters in height and are, of course, average values. For the safe loads, per sq in, on timbers, perpendicular to the grain, see Table VI.

Example 1. What is the safe load for a long-leaf yellow-pine column, 10 by 10 in in cross-section and 12 ft long, using a factor of safety of 5?

Solution. Area of cross-section = 100 sq in; safe load per sq in = 5 000/5 = 1000; 1 000 × 100 = 100 000 lb.

Example 2. It is required to support a brick wall weighing 80 000 lb by a Douglas-fir column 11 ft long. What should be the cross-section of the column?

Solution. As previously stated, for these conditions it would be wise to use a factor of safety of 6. Then the safe resistance per square inch of section-area = 4 500/6 = 750; 80 000/750 = 106 sq in required, about equivalent to a 10 by 10-in cross-section.

3. Strength of Wooden Columns or Struts Over Ten Diameters in Length. Formulas

Formulas for Wooden Columns. When the length of a column exceeds about ten times its least cross-dimension it is liable to bend under the load, and hence to break under a less load than would break it if it were shorter and of the same cross-section. To deduce a formula which will make the proper allowance for the length of a column has been the aim of many engineers, but their formulas have not always been exactly verified by actual results.

Until recently the formulas of Lewis Gordon and C. Shaler Smith have been used generally by engineers, but the extensive series of tests made by the Government testing-machine at Watertown, Mass., on full-sized columns, showed that these formulas did not agree with the results there obtained. James H. Stanwood in the year 1891 plotted the values of all the tests made at the Watertown Arsenal up to that time on full-size columns. From the results thus obtained

he deduced the following STRAIGHT-LINE FORMULA for long-leaf yellow-pine and white-oak columns:

$$\text{Safe load per square inch} = 1\,000 - 10 \times \frac{\text{length in inches}}{\text{breadth in inches}} \qquad (2)$$

The author has carefully compared this formula with the results of actual tests, and with other formulas,* and believes that for timber without serious defects and with not more than 10 or 12% of moisture, it meets the actual conditions as nearly as any other formula. He has therefore prepared Tables II III, IV and V for the strength of round and square columns of the sizes generally used in practice. Of course other formulas must be used when required by certain city building laws. For other sizes the loads can easily be computed by the formulas. For columns having bad knots or other defects, or more than 10 or 12% of moisture, or which are to be exposed to the weather or known to be eccentrically loaded, a deduction of from 10 to 25% should be made from the values given in the tables.

The loads for columns of other species of wood were computed by the following formulas of the same form as that of Formula (2):

For Douglas fir and spruce,

$$\text{Safe load per square inch} = 850 - 8.5 \times \frac{\text{length in inches}}{\text{breadth in inches}} \qquad (3)$$

For chestnut, hemlock, short-leaf yellow pine and white pine,

$$\text{Safe load per square inch} = 750 - 7.5 \times \frac{\text{length in inches}}{\text{breadth in inches}} \qquad (4)$$

For cedar, cypress, redwood, Norway pine and whitewood,

$$\text{Safe load per square inch} = 625 - 6 \times \frac{\text{length in inches}}{\text{breadth in inches}} \qquad (5)$$

In these formulas the breadth is the least side of a rectangular column, or the diameter of a round column. The round columns were computed for the half-inch, to allow for being turned out of a square column, of the next size larger. The formulas were used only for columns exceeding 12 diameters for Douglas fir and spruce, and exceeding 10 diameters for other woods.

4. Tables of Safe Loads for Wooden Columns

Tables II, III, IV and V give the safe loads in pounds for round and square wooden columns of different cross-sections and lengths and of different kinds of wood. They were computed from formulas as explained above and are for favorable conditions of material, seasoning and position in buildings.

* There are many formulas for the safe loads per square inch of cross-section of wooden columns. Among those frequently used are the following:

American Railway Engineering and Maintenance of Way Association,

$$P/A = S\,(1 - l/60\,d)$$

Department of Agriculture,

$$P/A = S\,(700 + 15\,l/d)/(700 + 15\,l/d + l^2/d^2)$$

Winslow Formula (Chicago Law),

$$P/A = S\,(1 - l/80\,d)$$

In these formulas, P is the safe load in pounds, A the area of the cross-section in square inches, P/A the safe load in pounds per square inch, S the safe end-bearing compression per square inch, l the length in inches and d the least side or diameter in inches. These formulas give smaller safe loads than those of Tables II, III, IV and V; but as the loads of these tables are to be DECREASED for unfavorable conditions and the loads determined from the three formulas mentioned INCREASED for favorable conditions, the results are about the same.

5. Eccentric Loading of Wooden Columns

General Principles. When the load on a short column or post is not axial, that is, when the column supports a girder on one side only, or when the weight from one girder is much more than that from the others, the load is said to be ECCENTRIC, and the distance from the point of application of the load to the axis of the column, denoted by p, is called the ECCENTRICITY of the load. It is evident that the stress in the column will increase with p, and that the total unit stress S, on the side of the column in which the compression is the greatest will be greater than for an equal axial load.

Formula for Eccentric Load. Suppose the eccentric load to be applied as shown in Fig. 1, then the sectional area of the required square or rectangular column may be computed by the following formula:

The sectional area of the column in square inches is

$$A = P/S + 6\,P_1 p/Sd \qquad (6)$$

in which A = sectional area in square inches
P = total load on column in pounds
P_1 = eccentric load in pounds
S = safe stress in pounds per square inch
p = distance from axis of column to center of bearing in inches
d = side of column parallel with girder, in inches

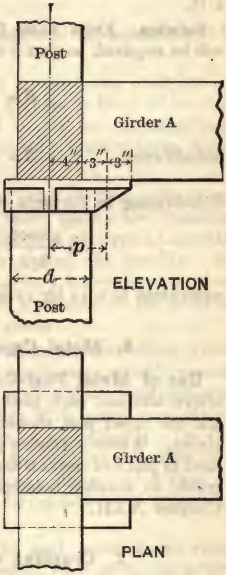

Fig. 1. Eccentric Load on Wooden Column

In assuming the value of S, the probable ratio of the side to the length of the column should be taken into account. Thus if it is probable that the length will not exceed 12 times the side, both being measured in inches, for oak, long-leaf yellow-pine or Douglas-fir columns, or 10 times the side for other woods, then the value of S for short columns may be taken. If the ratio will probably be greater than this, then the probable ratio should be roughly calculated and S computed for that ratio by the formula given for columns more than 10 or 12 diameters in length, as noted in preceding paragraphs.

Example 3. The lower post in Fig. 1 supports a total load on its cap-plate of 60 000 lb, including the reaction of 12 000 lb from girder A. What should be the size of the column if made of Douglas fir and if 12 ft in height?

Solution. As it is probable that the column will have to be 10 in square S may be taken from Table I. With a factor of safety of 5, this is equal to $4\,500/5 = 900$ lb per sq in. $P_1 = 12\,000$ lb, $d = 10$ in and p, the distance from the axis of the column to the center of bearing of the girder = 7 in. Then from Formula (6), the sectional area of the column is

$$A = \frac{60\,000}{900} + \frac{6 \times 12\,000 \times 7}{900 \times 10} = 66.6 + 56 = 122.6 \text{ sq in,}$$

about equivalent to a 12 by 12-in square column. From Table III, it may be seen that an 8 by 10-in column concentrically loaded will carry almost 60 000 lb.

Hence, the eccentric load from the girder increases the dimensions of the cross-section of the column from 8 by 10 to 12 by 12 in.

For wooden columns having a length of over 12 diameters for Douglas fir and spruce and over 10 diameters for other woods the safe load per square inch should be found by using Formulas (3), (4) or (5).

Example 4. What size will be required for a white-oak column, 14 ft in length to carry a total load of 56 000 lb, 16 000 lb of which act as an eccentric load from a girder, the distance from the center of bearing of the girder to the column being 2 in.

Solution. From Table II, it is probable that at least a 10 by 10-in column will be required, so that S must be calculated by Formula (2).

$$S = 1\,000 - 10 \times \frac{\text{length in in}}{\text{breadth in in}}$$

Substituting, $$S = 1\,000 - 10 \times \frac{168}{10} = 832 \text{ lb per sq in}$$

Substituting in Formula (6),

$$A = \frac{56\,000}{832} + \frac{6 \times 16\,000 \times 7}{832 \times 10} = 68 + 80 = 148 \text{ sq in}$$

equivalent to a 12 by 12-in column.

6. Metal Caps and Bolsters for Wooden Columns

Use of Metal Post-Caps. Whenever wooden posts are used in tiers, one above another, each post except the top one should have an iron cap-plate, and the upper post should be set on the cap of the post below and not on the girder. Where a wooden post supports a girder, only, a wooden bolster may be used in place of the cap but modern approved metal post-caps are always preferable to wooden bolsters. Details of post-caps and bolsters are shown in Chapter XXII.

7. Crushing of Wood Perpendicular to the Grain

Safe Unit Stresses. The bearing of wooden girders, the ends of columns resting on girders, and washers on truss-rods, should be proportioned so that the quotient obtained by dividing the load by the bearing area will not exceed the safe unit stresses given in Table VI.

Table VI. Safe Loads for Wood Perpendicular to the Grain

Kind of wood	Safe loads, lb per sq in	Kind of wood	Safe loads, lb per sq in
White oak	500	Cedar	200
Long-leaf yellow pine	350	Spruce	200
Douglas fir	200	Hemlock	150
Norway pine	200	Cypress	200
White pine	200	Redwood	150
Short-leaf yellow pine	250	Chestnut	250

8. Cast-Iron Columns*

Cast-Iron Versus Steel Columns. Although steel is being used more and more every year for columns in buildings, it will probably never entirely supplant cast iron for buildings of moderate height. For skeleton construction, however, when the height of the building exceeds twice its width, riveted steel columns, with riveted connections with the beams and girders, are unquestionably better; but for the larger proportion of buildings of moderate height, cast iron will probably have the preference for some time to come because it is more economical.

Advantages of Cast-Iron Columns. The commercial advantages which favor the use of cast-iron columns are these:

(1) **Cheapness.** As far as the cost of production is concerned, cast iron is cheaper than steel. This consideration alone often decides in favor of its employment. The raw material is easily transported as pig iron is sometimes brought over as ballast; so that competition with foreign countries keeps down the price.

(2) **Availability.** Cast iron is the most available form of iron. An iron-foundry requires no very elaborate plant, scarcely more than a few furnaces and sand molds, and moreover, no very extensive capital is required to operate it; consequently, the product may be obtained in almost any locality. In rolling-mills, on the contrary, the machinery must be very heavy in order that it may overcome the enormous pressure due to the resistance of the steel in rolling, and to operate it requires a great amount of power.

(3) **Readiness with Which it May be Obtained.** Columns and other structural members if made of cast iron may be obtained much more quickly than if made of steel. After the pattern has once been prepared, a dozen castings may be made almost as quickly as one, and with but very little extra cost, except that of the additional raw material and the expense of remelting it. On the other hand, columns and girders built up of rolled sections take considerably longer to make. Sections can be punched only one at a time, and if they do not happen to be of some standard length, they must be cut and fitted separately before all can be finally riveted together.

(4) **Physical Advantages.** Cast iron is one of the best materials to resist compression, its ultimate compressive strength being as high as 80 000 lb per sq in and even higher. Moreover, it can be molded into almost any desired form, and lugs, brackets and flanges may be cast upon a column all in one piece thus greatly simplifying the cost of erection. In fact, the ease with which the beam and girder-connections can be made is one of the chief reasons for the popularity of cast iron. Finally, it resists fire better than steel and it corrodes less easily. Because of this, its use is advocated by many for the wall columns of skeleton structures, as these columns are particularly liable to corrode. In the Mutual and Manhattan Life Insurance Company's Buildings in New York City, for example, the wall columns are of cast iron, whereas the interior ones are of steel.

Disadvantages of Cast-Iron Columns. The disadvantages of cast iron for columns are as follows:

(1) **Physical Disadvantages.** Cast iron is hard and brittle and cannot be punched or riveted, as the blows required in driving the rivets would very likely fracture the castings; consequently, all connections have to be made with bolts. A bolted connection even under the most favorable conditions is not very rigid,

* See, also, Chapter XIII, pages 445 to 447.

as it allows more or less lateral movement, which, in the case of a tall, narrow building, is a serious matter. Owing to the low tensile and shearing strengths of cast iron, the brackets supporting beams and girders are unreliable and require great skill in designing. (See pages 445 to 447.)

(2) Defects in the Castings and the Difficulties of Thorough Inspection. The castings themselves are subject to a number of serious defects. In the first place, owing to the shifting or floating of the cores, variations in the thickness of hollow castings are not infrequent; in fact, it is very difficult to avoid them even with the best care and workmanship. Moreover, there are apt to be concealed cavities, blow-holes or honeycomb, and foreign substances, such as cinders and sand, any of which may be on the inside of a casting, where a careful examination often fails to reveal them. The most critical condition, however, is that due to the uneven contraction of the metal during the process of cooling, the thin parts of the casting cooling and contracting more quickly than the thick ones, thereby giving rise to INITIAL STRESSES, at times of sufficient intensity to fracture the casting before any external loads whatever have been placed upon it. In many cases this trouble is due to faulty designing or to carelessness in handling the molds; yet, even under the most favorable conditions, it is so difficult to secure equal radiation from the molds in all directions that castings entirely free from inherent shrinkage-stresses are probably seldom produced.

9. Design of Cast-Iron Columns

Common Forms of Cast-Iron Columns. Figs. 2, 3 and 4 show some common forms of cross-sections of cast-iron columns. Columns of circular or rectangular cross-sections are always made hollow and the diameter should be made as large as possible, within reason of course; because of two columns

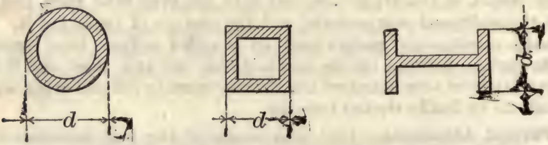

Fig. 2 Fig. 3 Fig. 4

Figs. 2, 3 and 4. Cross-sections of Cast-iron Columns

having the same area of cross-section, the one which, within certain limits, has the greater diameter, and consequently the thinner shell, is the stronger. The maximum thickness of shell is 1¾ or 2 in, because of the difficulty of keeping the core from shifting in columns of greater thickness; and the minimum thickness is ¾ in. The latter is a requirement of most municipal building codes. As the maximum limit of diameter, 16 in may be taken; beyond this, built-up steel columns can be used to better advantage and are less expensive. The minimum diameter permitted by most building codes is 5 in, and the unsupported length of the column is limited to 20 times the least diameter.

Hollow, Cylindrical Cast-Iron Columns. The most economical form of cross-section, as far as structural requirements are concerned, is the HOLLOW CIRCLE (Fig. 2). This form is generally used for interior columns; but for exterior columns it is not so desirable, because such columns cannot be bonded into walls so readily, and do not present the same facilities for the design of the beam and girder-connections as columns having the other forms of cross-sections.

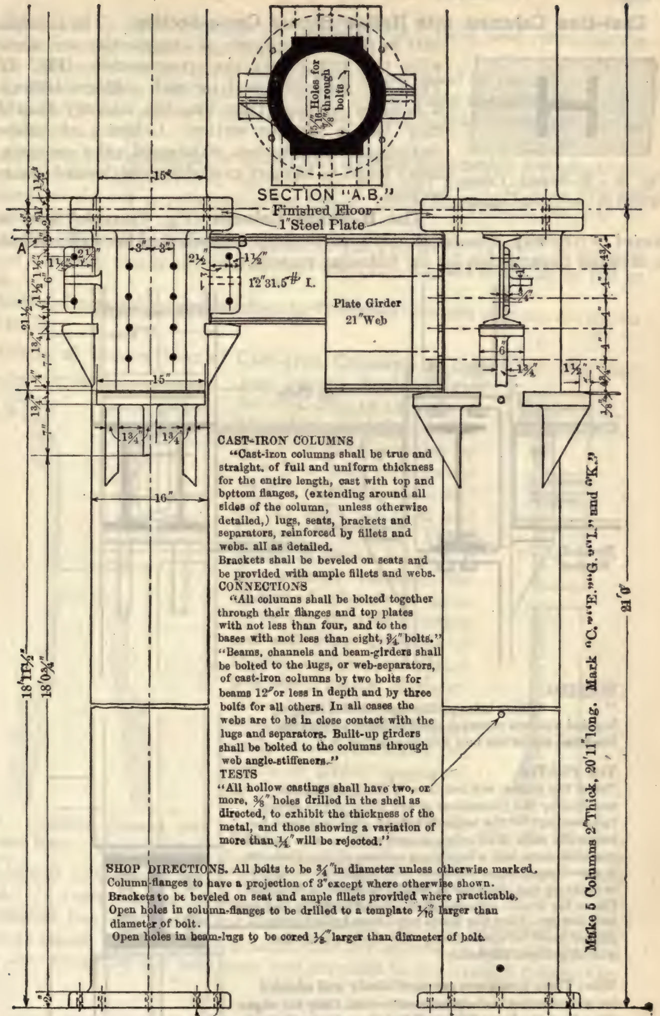

Fig. 5. Connections for Cylindrical Cast-iron Columns

Typical Connections for a Cylindrical Cast-Iron Column. Fig. 5 shows the details of a cylindrical cast-iron column with typical beam and girder-connections, dimensions and specification-notes. (See, also, details of connections, brackets, base-plates, etc., for cylindrical columns in Chapter XIII, Figs. 2, 3 and 7 and Table III of same chapter.)

Cast-Iron Columns with Hollow-Square Cross-Section. The columns next in point of economy of cross-section are those with the HOLLOW-SQUARE cross-section (Fig. 3). They are generally used for wall columns because it is easier to bond them into the masonry than if they had a circular section. Columns of hollow rectangular cross-section of unequal sides are sometimes found to be more available than those of square section.

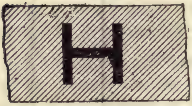

Fig. 6. H-shaped Cross-section of Cast-iron Column

The H-Shape Column (Fig. 4) ranks third in regard to economy of material. It is particularly well adapted for wall columns in skeleton construction for the following reasons:

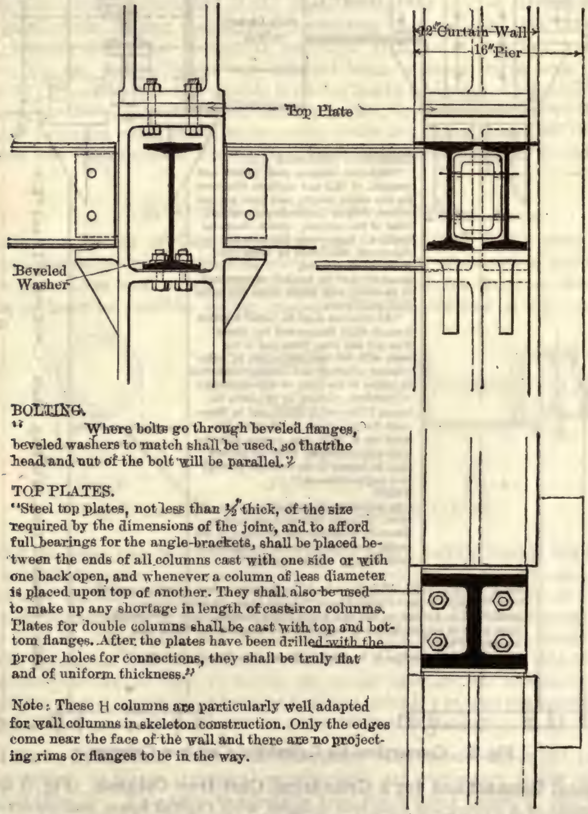

Fig. 7. Connections for H-shaped Cast-iron Column

(1) Being entirely open, with both the interior and exterior surfaces exposed, any inequalities in thickness can be readily discovered and the thickness itself

easily measured, thus obviating any necessity for drilling, and rendering the inspection of the columns much easier.

(2) The entire surface of the column may be protected by paint.

(3) When built in brick walls the masonry fills all voids, so that no open space is left; and if the column is placed as shown in Fig. 6, only its edges come near the face of the wall.

(4) Lugs and brackets can be cast on such columns more readily and effectively than on cylindrical columns, especially for wide and heavy girders, and the connections do not require projecting flanges, which are often in the way on cylindrical columns.

(5) An eccentric load may be applied to the web where its effect is less and where it is more evenly distributed than when it is applied to the outer rim or shell.

Details of connections and brackets for H-shaped cast-iron columns are shown in Fig. 7.

Details of Connections of Cast-Iron Columns. The bearings of a cast-iron column should always be faced true to the axis of the column, and the columns should be bolted together by four ¾-in bolts for columns 10 in in diameter or less, and by six bolts for 12-in and larger columns. Faced plates, as shown in Fig. 5, are inserted between the flanges of columns to make up for any shortage in length and also when a column of smaller diameter is placed over one of greater diameter. For convenience in erecting columns, the joint is generally placed just above the beams or girders supported by the columns.

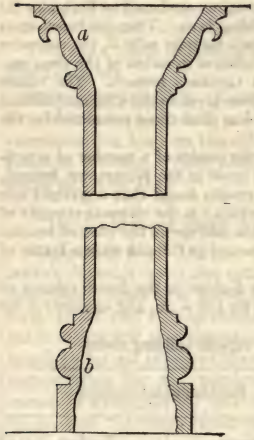

Fig. 8. Cast-iron Column with Cap and Base. Wrong Method

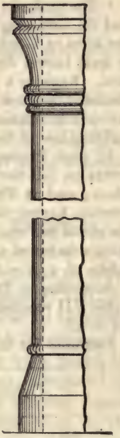

Fig. 9. Cast-iron Column with Cap and Base. Slight Projections

Projecting Caps and Bases. A column with ornamental cap and base should never be cast as shown in Fig. 8, that is, if it is to support a load. In every bearing column, the core should extend in a straight line from end to end. Plain molded caps and bases may be cast solid as in Fig. 9; but if more ornamental caps are desired, or heavy projecting bases, they should be cast separately and attached to the straight columns by screws.

10. Strength of Cast-Iron Columns. Formulas

Formulas for Cast-Iron Columns. The ULTIMATE RESISTANCE of cast iron to crushing is generally taken at 80 000 lb per sq in, and for posts, pintels, etc., where the length is not more than six times the diameter or breadth, it will usually be safe to assume a WORKING STRENGTH of six tons per square inch of metal. For longer posts or columns, the strength is affected by the ratio of

length to diameter, but to just what extent is not known with absolute certainty; hence all formulas for columns must be more or less theoretical. The consequence is that while a great many formulas have been published, there is none that is universally accepted. The two following Formulas* (7) and (8), however, are perhaps now more commonly adopted than any others, as they appear to agree as well as any with actual tests.

Formula for Hollow, Cylindrical, Cast-Iron Columns with Square Ends

Ultimate strength, in pounds

$$= \text{metal-area} \times \left[80\,000 \div \left(1 + \frac{\text{sq of length in in}}{800 \times \text{sq of diam in in}} \right) \right] \tag{7}$$

or

$$\text{Ultimate strength, in pounds} = \frac{80\,000\,A}{1 + l^2/800\,d^2}$$

in which A is the area of the cross-section in square inches.

* The tables in the handbook of the Cambria Steel Company are based on Formulas (7) and (8), and they have been adopted in the Boston building laws. They are based upon the form of Gordon's formula, which in turn is Rankine's formula with d, the diameter or least lateral dimension, substituted for r, the least radius of gyration of the cross-section. Rankine's formula is sometimes referred to as Gordon's formula. The values obtained by these formulas will be slightly in excess of those given in the Chicago building law (see tabulation in this footnote), and considerably less than those permitted by the building law of New York City, $S = 13\,000 - 30\,l/r$.

In 1898 Professor W. H. Burr made an analysis of the results of a number of experiments on full-size, hollow, cylindrical cast-iron columns made at the Watertown Arsenal, Mass., and at Phœnixville, Pa., and by plotting the results found that a straight-line formula having the equation $S = 30\,500 - 160\,l/d$, in which S is the ultimate strength of the metal per square inch of column-area, represented the average of the plotted results. With a factor of safety of 4 this would become $S = 7\,625 - 40\,l/d$ and with a factor of safety of 5, $S = 6\,100 - 32\,l/d$.

According to Professor Burr's analysis the values for S given in the fourth column of Table VII represent a factor of safety of a little over 4 for $l/d = 20$, and of nearly 7 for $l/d = 36$.

Formulas for finding the values of S according to the various building codes.

Cylindrical columns		Rectangular columns	
Chicago	Boston	Chicago	Boston
$\dfrac{10\,000}{1 + \dfrac{l^2}{600\,d^2}}$	$\dfrac{10\,000}{1 + \dfrac{l^2}{800\,d^2}}$	$\dfrac{10\,000}{1 + \dfrac{l^2}{800\,d^2}}$	$\dfrac{10\,000}{1 + \dfrac{l^2}{1\,066\,d^2}}$

The New York City Building Code Formula is

$$S = 13\,000 - 30\,l/r$$

Compared with the results of tests that have been made on full-size cast-iron columns it has been shown that while in Chicago a factor of safety of 8 is allowed, the actual factor of safety is a little over 4, that in Boston it is slightly under 4, while in New York it is a trifle over 6. Great care, therefore, should be taken in the calculations for cast-iron columns, as the above comparison shows.

A series of tests on full-size cast-iron columns and brackets was made under the direction of Stevenson Constable, in December, 1897, a report of which, with illustrations, may be found in the Engineering Record for January 8 and 22, 1898.

Formula for Hollow, Rectangular, Cast-Iron Columns with Square Ends

Ultimate strength, in pounds

$$= \text{metal-area} \times \left[80\,000 \div \left(1 + \frac{\text{sq of length in in}}{1\,067 \times \text{sq of least side in in}} \right) \right] \qquad (8)$$

or

$$\text{Ultimate strength, in pounds} = \frac{80\,000\,A}{1 + l^2/1\,067\,d^2}$$

in which A is the area of the cross-section in square inches

Formula for Solid, Cylindrical, Cast-Iron Columns

Ultimate strength, in pounds

$$= \text{metal-area} \times \left[80\,000 \div 1 + \frac{\text{sq of length in in}}{266 \times \text{sq of diam in in}} \right] \qquad (9)$$

or

$$\text{Ultimate strength, in pounds} = \frac{80\,000\,A}{1 + l^2/266\,d^2}$$

in which A is the area of the cross-section in square inches.

For H-shaped columns use formula (7), taking d as the least side.

THE SAFE LOAD is generally taken at one-eighth of the ultimate strength or breaking-load.

Eccentric Loading. Cast-iron columns should not be loaded with a heavy, ECCENTRIC LOAD, that is, a load applied on one side of the column without a corresponding load on the other side, as cast iron is unable to resist very great bending stresses. (See, also, eccentric loading of wooden and steel columns, pages 453 and 485.)

11. Tables of Safe Loads for Cast-Iron Columns. Examples

Explanation of Tables. As the allowable pressure PER SQUARE INCH OF METAL depends upon the ratio of length to diameter, without regard to actual dimensions (that is, it would be the same for a column 6 in in diameter and 12 ft long, as for one 8 in in diameter and 16 ft long), it is practicable to prepare a table which will give the value of the terms of Formulas (7) and (8) inclosed in brackets for all ratios of diameter to length, and thus simplify very much the computation for any particular column. Table VII has been computed by means of Formulas (7) and (8) for ratios of length to diameter varying from 8 to 36, and the same result will be obtained by using the values given in this table as by using the corresponding formula. To use this table it is only necessary to divide the length of the column by the least thickness or diameter, both in inches, and opposite the number in the first column of the table coming nearest to the quotient, find the SAFE STRENGTH PER SQUARE INCH for the column. This load is multiplied by the METAL-AREA in the cross-section of the column and the result is the SAFE LOAD for the column. Examples (5) and (6) will illustrate the use of Tables VII to X.

Example 5. What is the safe load for a 10-in hollow, cylindrical cast-iron column, 15 ft long, the shell being 1 in thick?

Solution. In this case the ratio l/d, which is the length of the column divided by the diameter, both in inches, is 18, and opposite 18 in Table VII the safe load per square inch for a cylindrical column is found to be 7 117 lb. The metal-area of the column, from the table of areas of circles, page 42, is equal to the area of a 10-in circle minus the area of an 8-in circle, or, 78.53 − 50.26 = 28.27 sq in. Multiplying these two together, for the safe load of the column the result is 28.27 sq in × 7 117 lb per sq in = 201 197 lb, or about 100.5 tons.

Tables VIII, IX and X. To still further facilitate computations, Tables VIII, IX and X, have been prepared, which give at a glance the safe loads, based on a factor of safety of 8, for columns of the more common sizes and lengths. For lengths between those given in the tables sufficiently accurate results may be obtained by interpolation. For any other factor of safety, multiply the safe load given in the table by 8, and divide by the new factor of safety.

Example 6. What is the safe load for a 9-in hollow, cast-iron column of square cross-section 12 ft long, the shell being 1 in thick?

Solution. From Table IX, the safe load is 129 tons. The same result may be obtained by using Table VII. The ratio l/d in this case is $144/9 = 16$ and the corresponding safe load in pounds per square inch is 8 064. The area of the column is 32 sq in. Hence, the safe load is 32 sq in $\times$ 8 064 lb per sq in = 258 048 lb, or 129 tons, which agrees with the safe load given in Table IX for the same column.

Table VII. Breaking-Loads and Safe Loads in Pounds per Square Inch for Hollow, Cylindrical and Hollow, Rectangular, Cast-Iron Columns

Calculated by Formulas (7) and (8)

Length in inches divided by external breadth or diameter	Breaking-weight in pounds per square inch		Safe loads in pounds per square inch. Safety-factor 8	
	Cylindrical	Rectangular	Cylindrical	Rectangular
8	74 074	75 470	9 259	9 433
9	72 661	74 350	9 082	9 293
10	71 110	73 126	8 888	9 140
11	69 505	71 870	8 688	8 983
12	67 800	70 487	8 475	8 811
13	66 060	69 084	8 257	8 635

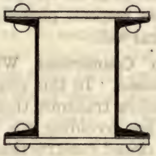
12. Types, Forms and Connections of Steel Columns

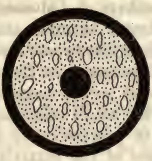
Use of Steel Columns, Struts, Trusses, etc. Owing to the many advantages of built-up steel columns over cast-iron columns, especially for all buildings, and to the great reduction that has taken place in the cost of steel construction, built-up columns are now very extensively used in buildings of even moderate height; and for skeleton construction, or for buildings exceeding six stories in height, they are certainly much to be preferred to cast-iron columns. Steel trusses, also, are now much more commonly used in buildings than in former years, so that the architect must have at hand data for designing them and for computing their strength. In the following pages the author has endeavored to cover the subject of columns and struts quite completely, to furnish such data as will enable the designer to decide upon the shape of column or strut it is best to use, and also to determine the sizes and sections of such columns with the least labor.

Types and Forms of Steel Columns. The following are cross-sections of the majority of steel columns in general use, arranged in the order of their simplicity of construction, that is, the number of rows of rivets they require:

Bethlehem H column
No rivets



Channel-column with plates or lattice-bars
Four rows of rivets



Lally steel-concrete column
No rivets

Plate-and-angle column with side plates
Six rows of rivets

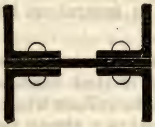


Plate-and-angle column
Two rows of rivets

Box column
Eight rows of rivets

Considerations Governing the Selection of Steel Columns. There are considerations other than simplicity of construction which sometimes govern the selection of a column. Some of the most important of these are explained in the following paragraphs:

(1) **Cost and Availability of Material.** I beams, channels, plates and angles are the most common commercial sections. They are easily rolled and are manufactured by all of the large mills. They are reasonable in price and may be obtained promptly in large numbers in any locality where a steel building is likely to be erected. Patented sections, or the product of one mill, do not, as a rule, fulfill these conditions.

(2) **Amount of Labor Required and Facility With Which it can be Performed in Shop and Field.** In the shop the complexity of the column-section and the number of pieces of which it is composed greatly affect the cost of labor. If there are numerous small pieces such as lattice-bars, splice-plates, etc., each of which requires cutting and fitting together, with frequent handling, the cost is proportionately great. The cost of a column depends, also, largely upon the number of rivets required and whether they can all be driven by machine so as to avoid the slower and more expensive hand-riveting. The same general remarks apply to labor in the field; the connections should be as simple as possible, the rivets easy of access and as few in number as is consistent with strength.

(3) **Simplicity of Connections Between Column and Supported Members.** This is quite an important consideration in the design of a large building and sometimes governs the choice of the section to be used. Where there are four beams to a column, on opposite sides, and all of the same height, a satisfactory connection can be made with almost any section; but where the beams are spaced irregularly, both in regard to position in plan and to height, and where eccentric loads must be provided for, it is very important that the section of the column itself affords as great an opportunity as possible for the connections of the beams. In this respect, possibly, closed sections are inferior to open sections having a central web.

(4) **Adaptability to Connections Which Transfer Compressive Stresses Directly to Axis of Column.** In this respect, also, sections of an open construction, in which the girders transmit their loads almost directly to the central axis of the column, thus avoiding the disadvantage of eccentric loading, are superior to those of a closed construction.

(5) **Adaptability to Changes in Thickness of Metal in Members of Columns, to Suit Different Loads in Different Stories.** It is not desirable to make the columns carrying the upper floors of a building very small, since the beams and girders supporting the upper floors are usually of the same dimensions as those of the lower floors and consequently require just as heavy and secure connections. It is almost impossible to make such connections with small columns, and consequently, in order to reduce the area of a column in proportion to a lighter load to be carried, it is better to reduce the thickness of the material used and to keep the general dimensions of the section the same.

(6) **Adaptability to Fire-Proof Covering.** Closed sections in general can be more compactly fireproofed than open sections.

General Considerations Affecting the Choice of Steel Columns. It is almost impossible to say that any one of the foregoing types of steel columns is superior to the others. Each has its own good points, and the column whose section has theoretically the best distribution of material may not always be the best one to use, because of the eccentric loads to be carried, or because of other conditions. The choice in most cases will depend upon the personal views of the designer, as well as upon the local conditions as to cost and manufacture, promptness of delivery and the details of the problem. Further descriptions of the different columns, and also the special advantages claimed for them, are given in the following pages.

Steel-Column Connections. When steel columns were first designed it was customary to use cap-plates to connect the story-lengths, and the beams or girders often rested upon these plates. In modern practice, however, the column-joint is generally placed just above the beams and girders for convenience in erection and the plates are often omitted The columns are closely fitted

together with milled ends, and splice-plates are riveted to the sides or flanges as shown in the illustrations of typical steel-column details, Figs. 17 and 18. As it is impossible in these pages to include the subject of column-connections in anything but a general way, the only attempt that has been made in this direction is to illustrate common forms of connections that have been used with different kinds of columns. These will be found in the description of columns in the following pages.

Number of Rivets Required. No general rule can be given for the number of rivets and size of the brackets required for column-connections, as the loads to be supported vary in different buildings and in different parts of the same building. The number of rivets required in each connection must therefore be determined by the rules given in Chapter XII for designing riveted joints. Connections for single beams, however, will generally require the same number of rivets as are given for beam-connections (Chapter XV, page 617). The allowable stress for rivets in column-connections is generally taken at 10 000 lb per sq in for single shear and 18 000 or 20 000 lb per sq in for bearing. (See Tables II and III, pages 418 and 419, Chapter XII.)

Spacing of Rivets. Steel columns fail either by deflecting bodily out of a straight line or by the buckling of the metal between rivets or other points of support. Both actions may take place at the same time, but if the latter occurs alone, it may be an indication that the rivet-spacing or the thickness of the metal is insufficient. The rule has been deduced from actual experiments upon riveted columns that the distance between centers of rivets should not exceed, in the line of stress, sixteen times the thickness of metal of the parts joined, with a maximum spacing of 6 in, and that the distance between rivets or other points of support, at right-angles to the line of stress, should not exceed thirty-two times the thickness of the metal. The usual practice in designing columns is to space the rivets the minimum distance on centers at both ends, for a length equal to twice the least dimension of the column, with the maximum spacing of 6 in between.

Steel-Pipe Columns.* Steel-pipe columns are used for interior construction to carry beams and girders supporting floors, walls and chimneys in all classes of buildings, such as tenements and apartment-houses, factories, garages, churches, warehouses, etc. A particular demand for steel-pipe columns is at the angles of show-windows in mercantile buildings. In buildings of moderate height the floor-joists are usually supported by the side walls and the columns have to support only a relatively light wall above. For such places wrought-steel pipes may be advantageously used for the columns. They may be used, also, for the columns supporting the roof of one-story buildings. In the Borough of Brooklyn, New York City, pipe-columns are calculated according to the formula $S = 14\,000 - 80\,l/r$, in which S, l and r have values as explained below for the New York City formula. If the columns are filled with concrete, the area of the cross-section of the concrete is multiplied by 500 and the product added to the load supported by the pipe. (See, also, paragraph on Lally Columns, page 477.) This formula gives a factor of safety of four. The New York Bureau of Buildings uses the formula, $S = 15\,200 - 58\,l/r$, in which S is the permissible unit fiber-stress, l the length in inches and r the radius of gyration of the cross-section of the pipe. This gives a carrying capacity about 10% greater than that of the Brooklyn formula. In Philadelphia, pipe-columns are allowed to carry about 25% more than is allowed in Brooklyn. Where pipe-columns are filled

* Much valuable data relating to steel-pipe columns was furnished the Editor-in-chief by P. C. Patterson and J. A. McCullough of the National Tube Company, Pittsburgh, Pa.

with concrete the cast cap and base are secured to the pipe in each case by concrete which is reinforced internally by a pipe of smaller diameter. Where these steel-pipe columns filled with concrete are used, care should be taken

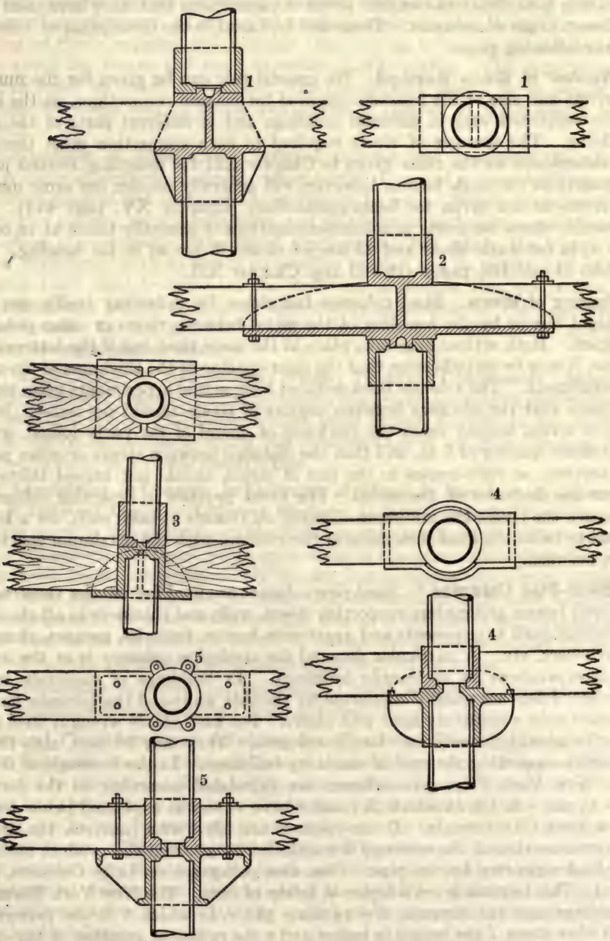

Fig. 10. Connections, Caps and Bases for Steel-pipe Columns

that the pipes are entirely filled, and that there are no air-spaces in the concrete. These concrete-filled columns, sometimes reinforced with smaller pipes, have a large carrying capacity. Pipe-columns may have their supporting power

about doubled in many cases by concrete filling. (See, also, paragraph on Lally Columns, page 477.) One type of steel post-cap used in connection with pipe-columns to carry wooden girders is shown in Figs. 62 and 63 of Chapter XXII. There are many other forms of cast and wrought caps for pipe-columns. The

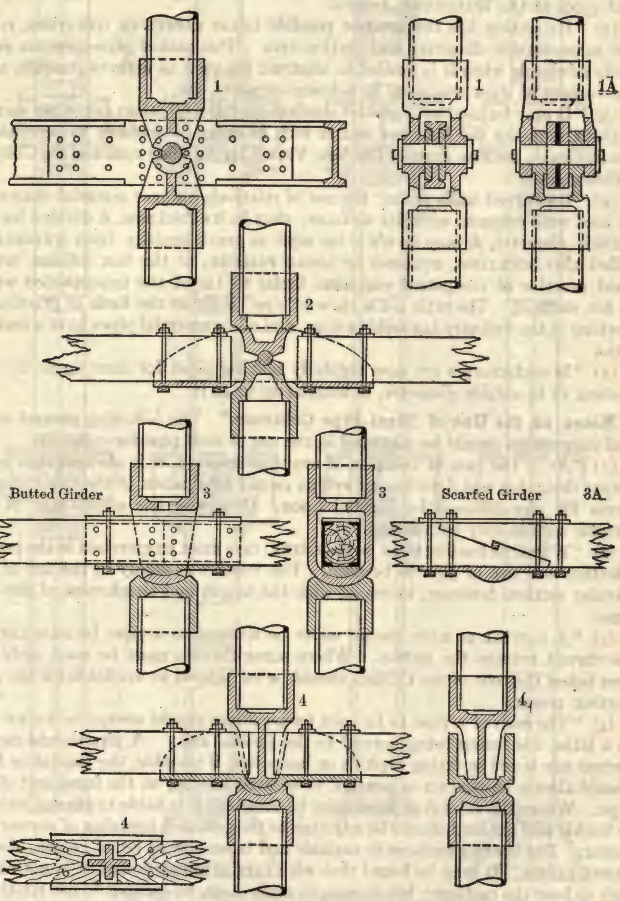

Fig. 11. Connections, Caps and Bases for Steel-pipe Columns

design of proper caps and bases is the most difficult part of adapting tubular columns to practical problems in building-construction. Figs. 10 and 11 show various forms of steel-pipe column-connections, caps and bases sufficiently suggestive to enable a designer to properly develop their details.

Advantages of Steel-Pipe Columns.* A wrought-steel pipe when used as a column generally has the following advantages:

(1) "It will support a greater load per square inch of cross-section than any other shapes and styles of mild-steel columns of the same SLENDERNESS-RATIO, l/r, for most of the columns of different slenderness-ratios recently tested (1908 and 1909) at the Watertown Arsenal.

(2) "Its section has the greatest possible LEAST RADIUS OF GYRATION, r, for the same outside diameter and section-area. This makes pipe-columns especially advisable when it is desired to obstruct the view as little as possible, as in the corners of show-windows, in balcony-supports, etc.

(3) "It may be used with greater slenderness-ratio, l/r, than any other section without reducing the load per square inch in order to conform to permissible loading-rules, such as those of the New York City building code and the Chicago building code.

(4) "Its curved walls permit the use of relatively thinner material than may be used with columns with flat surfaces; that is, its thickness, t, divided by the outside diameter, d, may be $t/d = 1/80$ with as great security from WRINKLING, called also BUCKLING, BULGING or LOCAL FAILURE, as the box column, which good practice of competent engineers limits to $1/50$ of the unsupported width of flat surfaces. The ratio $t/d = 1/80 = 1/4''/20''$ is about the limit of practicable working of the ordinary lap-weld process, and all commercial pipes have a smaller ratio.

(5) "Manufacturers are now regularly making pipes for sizes up to and including 16 in outside diameter, in lengths up to 40 ft."

Notes on the Use of Steel-Pipe Columns.* The following general notes and suggestions should be observed in the use of steel pipe for columns:

(1) "As in the case of columns of any construction, it is obvious that competent designing and detailing as well as proper fabrication of the END-CONNECTIONS for pipe-columns be insisted upon. Otherwise the advantages of the circular section may be nullified.

(2) "When the loading must be ECCENTRIC care must be exercised in the proper selection and size of pipe to be used. The relative economy in the use of the circular section, however, increases with the length and slenderness of the column.

(3) "A CAPITAL or BASE should never be screwed to a pipe, because cutting the thread reduces the section. Where screw-threads must be used, only the area below the root of the threads should be considered as available for the supporting power.

(4) "The ends of a pipe to be used for a column should always be FACED OFF in a lathe, the facing being normal to the general axis. A pipe should not be turned nor bored in fitting capitals or bases but, if possible, the capital or base should always be FORCED or SHRUNK to an even bearing on the faced end of the pipe. Where the capital or base must be inserted, it is liable to start a wrinkle or buckle and the load should be adjusted to the probable lessening of supporting power. The bearing surfaces in capitals and bases should be, of course, always LATHE-FACED. It may be found that with careful foundry-work it is not necessary to bore the castings; but it may, in some cases, be cheaper to use relatively poor foundry-work and bore the castings, as well as face the seats.

(5) "PIN-ENDS or BALL-AND-SOCKET ENDS are generally preferable to flat of fixed ends for a slenderness-ratio l/r, of 100 or less, because tests show that

* From notes by Professor Thomas Nolan on the subject of Steel-Pipe Columns, in Kidders' Building-Construction and Superintendence, Part II, Carpenters' Work, Ninth Edition.

columns so fitted usually carry heavier loads before failure. This is increasingly evident as l/r decreases. Any form of end-connection of column that may cause a flexure from a failing floor may endanger the whole structure.

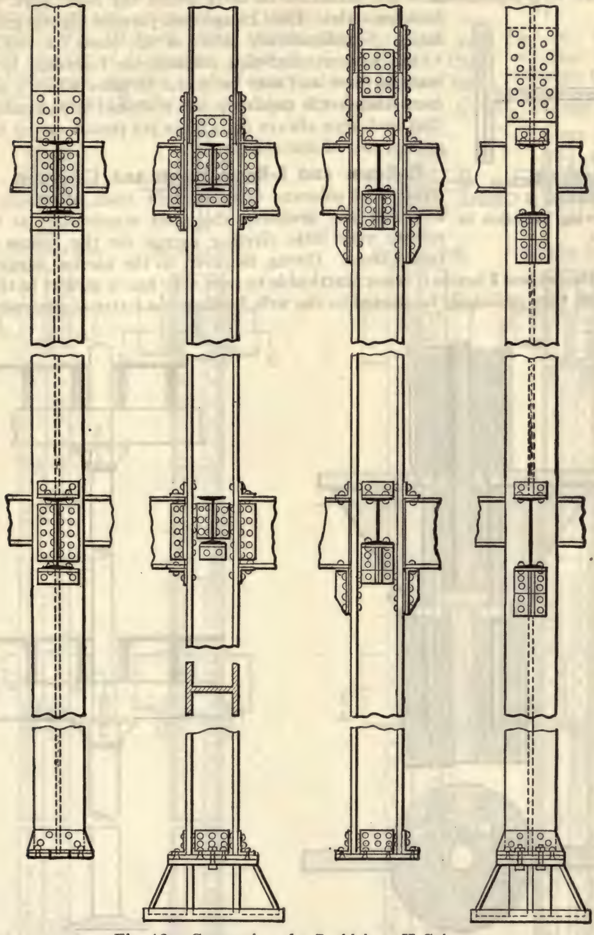

Fig. 12. Connections for Bethlehem H Columns

(6) "All columns should have sufficient STIFFNESS to safely withstand the chance deflecting forces to which they may be exposed. This usually involves considerations of eccentricity as well as of flexure due to transverse load.

(7) "It is desirable to adhere always to the trade sizes of pipe known as MERCHANT, STANDARD, EXTRA STRONG, DOUBLE-EXTRA STRONG, CASING, BOILER-

TUBES, etc., and avoid special production which usually entails delays and special prices."

(8) Tables XII and XIII give the safe loads which STANDARD and EXTRA-STRONG steel-pipe columns are permitted to carry under the New York City building code. The Chicago code permits slightly greater loads. Supplementary tables of safe loads for DOUBLE-EXTRA STRONG steel-pipe columns are furnished by the manufacturer and may be useful in cases where a minimum diameter is required; but it should be remembered that such pipe always costs more per pound, owing to its greater cost of manufacture.

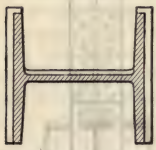

Fig. 13. Section of Bethlehem H Column Showing Variation in Area

H-Beam and I-Beam Struts and Columns. For struts and columns carrying light loads, H BEAMS and I BEAMS are probably the most economical, as they require very little riveting except for the splices and connections. Owing, however, to the narrow flanges of even the deepest I beams it is not practicable to rivet very heavy girders to them; nor can they ordinarily be riveted to the web, because the latter is generally so

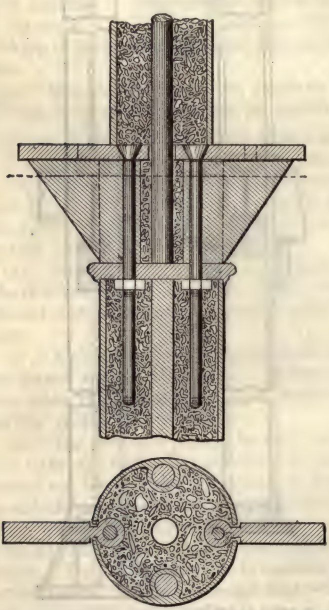

Fig. 14. Concrete-filled Lally Steel Column

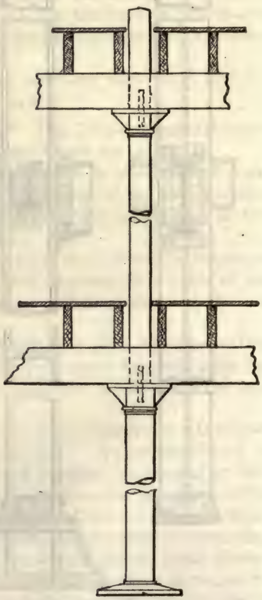

Fig. 15. Lally Column. Typical Connections

thin that too many rivets will be required for the connection. Tables XVII is a table of safe loads for the Carnegie steel H BEAMS or I BEAMS used as columns.

Bethlehem Columns. As far as shop-work is concerned the BETHLEHEM COLUMNS are just as economical as the ordinary **H**-beam or **I**-beam columns as they, also, are rolled and not built up or assembled. The only fabrication required is that for the splice-plates and connections. Typical connections are shown in Fig. 12 from which the simplicity of detail and small amount of fabrication required are apparent. They are, moreover, superior to the **I**-beam columns because they afford a wider flange for attaching the beams and girders, besides being

TYPICAL ANGLE-COLUMN
Bearing on steel

Fig. 17.* Connections for Steel Plate-and-angle Columns

* From Pocket Companion, 1915 Edition, Carnegie Steel Company, Pittsburgh, Pa.

more economical of cross-section. Bethlehem columns are rolled in four sizes, 8, 10, 12 and 14 in in width, but by spreading the rolls, as shown in Fig. 13, the section-area of each width can be increased considerably. The

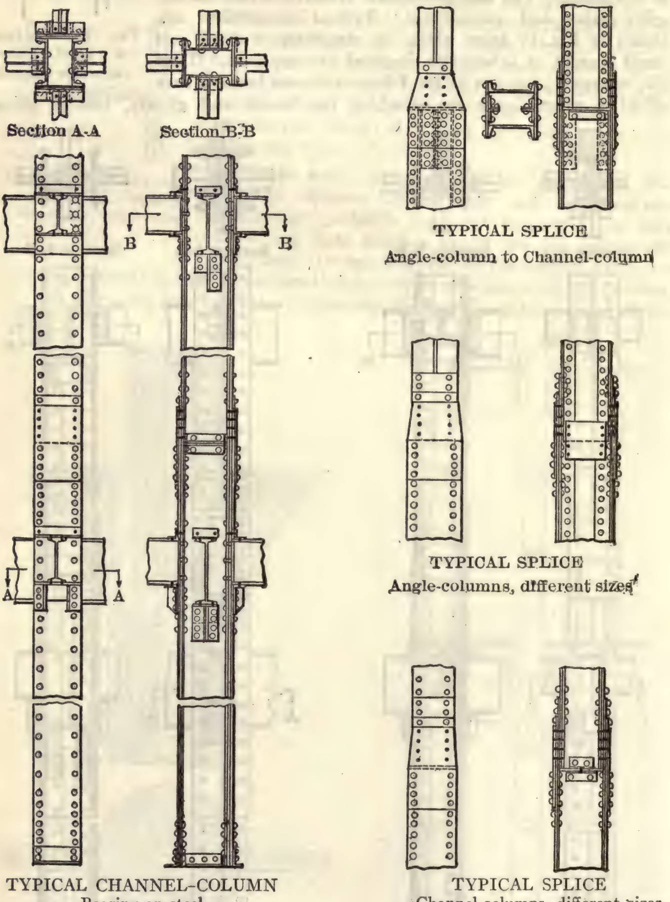

Fig. 18.* Connections for Steel Plate-and-channel Columns

section-areas of columns of the largest size may also be increased by riveting side plates to the flanges. Tables of DIMENSIONS and PROPERTIES of Bethlehem rolled steel columns and of the SAFE LOADS they will carry are given in Tables XVIII to XXI. Although these columns have been rolled in Germany since

* From Pocket Companion, 1915 Edition, Carnegie Steel Company, Pittsburgh, Pa.

1902, it was not until the establishment in 1908 of the larger improved mills at Bethlehem, Pa., that these sections became available for use in this country. They are gradually superseding plate-and-angle and box columns, particularly those of the smaller sizes.

Lally Columns. LALLY COLUMNS (see, also, paragraphs on Steel-Pipe Columns, page 469) are patented columns made with a circular steel shell, as shown in Fig. 14, and filled with a concrete composed of sand, cement and blue trap-rock, and thoroughly compressed. The larger columns have, in addition, a steel reinforcement, which makes a light, but strong support. They are in many buildings replacing masonry piers for supporting girders because of the saving in space, and are extensively used in mill-construction. Typical connections are shown in Fig. 15. The safe carrying capacities in tons are given in Tables XXII and XXIII, page 516.

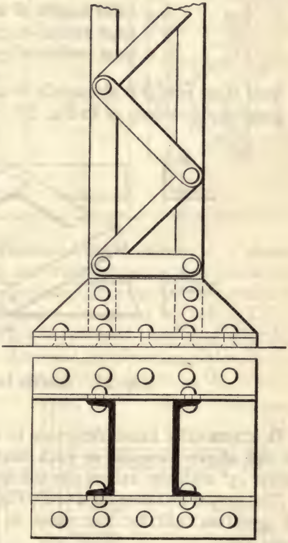

Fig. 19. Steel Channel-column with Lattice-bars

Plate-and-Angle Columns. Four angles and a plate riveted together as shown in Fig. 16 are now being extensively used in building-construction, particularly for columns having an unsupported length of less than 90 radii; also for the outer columns in steel mill-buildings, and for light columns supporting the roofs of railway stations, etc. Columns with this form of cross-section are especially convenient for making beam and girder-connections and for splicing, and are also well adapted to resist eccentric loads. The width of the plate is generally such that the LEAST RADIUS OF GYRATION is in the direction r_2, and this radius may be obtained directly from Tables XV and XVII, pages 370 and 372.

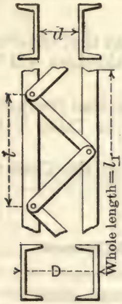

Fig. 20. Spacing of Lattice-bars in Channel-columns

Channel-Columns. Typical COLUMN-DETAILS for plate-and-angle and channel-columns, taken from the Carnegie Pocket Companion, 1915 edition, are shown in Figs. 17 and 18 and represent current practice in office-building construction.

Lattice-Columns. Two channels, set back to back, at such a distance that the radii of gyration will be equal about both axes, and connected by lattice-bars, as shown in Fig. 19, make a very desirable column for moderate loads, as in the upper stories, or in buildings of three or four stories in height. For greater loads, short cover-plates may be riveted to the flanges in place of the lattice-bars. Such columns are very satisfactory, especially for making connections.

Rule for Latticing of Channels and Angles. When channels are connected by lattice-work, as in Fig. 20, in order that there may not be a tendency

in the channels to bend between the points of bracing, the distance l should be made equal to the total length of the strut multiplied by the least radius of gyration of a single channel, and the product divided by the least radius of gyration for the whole section; or,

$$l = rl_1/r_1$$

in which l = length between points of bracing;
l_1 = total length of strut;
r = least radius of gyration for a single channel;
r_1 = least radius of gyration for the whole section.

This same rule will also apply to angles, although with them the lattice-work is generally doubled, as in Fig. 21.

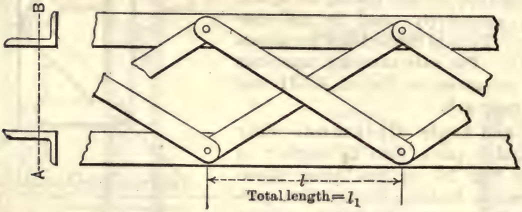

Fig. 21. Double Lattice-bars on Angle-columns

It is generally found desirable to make the distance l less than that obtained by the above formula, or such that the inclination of the lattice-bars will be about 45° with the axis of the column or strut.

The proper distance for d or D, Fig. 20, for a pair of channels, so that the radius of gyration will be the same in both directions, is given in Table VIII, page 359.

The following tabulations are taken from the Handbook of the Cambria Steel Company, 1915 edition.

Sizes of Lattice-Bars to be Used with Latticed Channel-Columns

Depth of channels	Dimensions of lattice-bars		Weight of lattice-bars per foot	Center of hole to end of bar, a	Distance center to center of rivets, d		
	w	Thickness			Maximum		Minimum
in	in	in	lb	in	ft	in	in
6	1½	¼	1.28	1⅛	0	11½	6⅝
7	1¾	¼	1.49	1⅛	1	1½	7⅝
8	2	5/16	2.12	1¼	1	3	8 11/16
9	2	5/16	2.12	1¼	1	4½	9½
10	2	⅜	2.55	1¼	1	6½	10 11/16
12	2¼	⅜	2.87	1⅜	1	10½	13
15	2½	⅜	3.19	1½	2	2½	15 5/16

Sizes of Stay-Plates to be Used with Latticed Channel-Columns

Minimum size of stay-plates at ends of columns			Weight of minimum stay-plates	Diameter of rivets
b	Thickness	*l*		
in	in	in	lb	in
8¼	¼	7½	4.38	⅝
9¼	¼	10	6.55	⅝
10½	5/16	9	8.37	¾
11¼	5/16	12	11.95	¾
12¼	⅜	12	15.62	¾
14¼	⅜	15	22.73	¾
16¼	⅜	15	25.90	¾

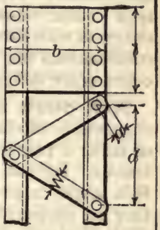

Plate-and-Angle and Box Columns. Plate-and-angle columns, as shown in Fig. 16, requiring but two rows of rivets are very economical columns for buildings of moderate height, as they afford excellent opportunities for connecting the beams and girders. Tables of SAFE LOADS are given in Table XXIV of this chapter. When a more compact section is required than that afforded by the larger sizes, the section-area may be increased by riveting plates to the angles as shown in Fig. 22 which is a section of one of the columns in the Munic-

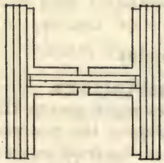

Fig. 22. Heavy Plate-and-angle One-web Column

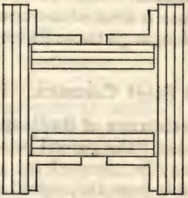

Fig. 23. Heavy Plate-and-angle Two-web Column

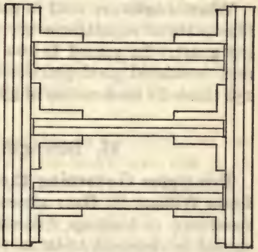

Fig. 24. Heavy Plate-and-angle Three-web Column

ipal Building, New York City. This, however, greatly increases the expense of the shop-work, and it is therefore usually more economical to substitute Bethlehem **H** columns, or channel or box columns. For high buildings or heavy loads, where the required sectional areas of columns are greater than can be obtained by using channel-columns or Bethlehem columns without flange-plates, BOX COLUMNS made of plates and angles, as shown in Fig. 23, which is one of the columns in the Bankers' Trust Company Building, New York City, will probably be found to be more satisfactory. The thickness and number of web-plates and flange-plates can be varied with the load to be supported. Ordinary connections for BOX COLUMNS are the same as those for CHANNEL-COLUMNS, shown in Fig. 18. For the tallest buildings and heaviest loads box columns with TRIPLE WEBS as shown in Fig. 24 are the best. They are used in the highest buildings erected, such as the Masonic Temple in Chicago, and the Bankers'

Trust Building, the Municipal Building, the Woolworth Building and the Metropolitan Tower in New York City. Fig. 24 is a cross-section of one of the columns in the last-mentioned building. Details of a similar column used in the Bankers' Trust Company Building are shown in Fig. 7 on page 342. It is of course impracticable to give tables of SAFE LOADS for PLATE-AND-ANGLE COLUMNS with flange-plates and for BOX COLUMNS, owing to the great variety of combinations that can be used, but Example 10 of this chapter shows how the columns are designed and their strength determined. (See page 485.)

Steel Struts in Trusses. These are generally made of a pair of latticed channels, or of channels and plates for heavy trusses with pin-connections, and of either a pair of light channels or a pair of angles with uneven legs for light trusses. For roof-trusses having a span not exceeding 80 ft, a pair of 4 by 6 by ¾-in angles is generally sufficient for any of the compression-members unless they are subjected to TRANSVERSE STRESS; and the minor struts are very often made of a pair of 3½ by 2½ by ¼-in angles. The angles are placed from ½ to ¾ in apart to permit the filler-plates used at the joints to go between them. For compression-members subject to transverse stress a pair of channels generally offers the best section. If necessary the channels can be reinforced by plates at the top and bottom. A pair of angles, with a deep web-plate riveted between, is often used for the principles of Fink trusses where they are subject to a slight transverse stress. (See, also, Fig. 6, page 1146.) For very light compressive stresses and for short members a single angle is sometimes used; but this is not considered good practice, as it causes eccentric loading on the gusset-plates at the truss-joints. A pair of small angles, or some other combination with a symmetrical cross-section should always be used for truss-members.

Where angles are used in pairs they should be connected by a rivet and small filler-plate or separator every two feet in length, to prevent them from springing apart. In regard to the maximum length of steel struts in trusses it is not considered good practice to use a strut whose unsupported length exceeds 150 times its least radius of gyration, or 50 times its least width.

13. Strength of Steel Columns. Formulas

Principles Governing the Resistance of Built-up Steel Columns. Professor William H. Burr states * that "the general principles which govern the resistance of built-up columns may be summed up as follows: the material should be disposed as far as possible from the neutral axis of the cross-section, thereby increasing the radius of gyration, r; there should be no initial internal stress; the individual portions of the column should be so firmly secured to each other that no relative motion can take place, in order that the column may fail as a whole, thus maintaining the original value of r." The experiments made by Professor Burr indicate that a closed column is stronger than an open one. It should also be remembered that any column such as an **I** beam, channel, or angle, the cross-section of which has a maximum and a minimum radius of gyration, is not economical for use under a single concentric load, as the minimum radius of gyration must be used in the calculation, and part of the material is to a certain extent wasted when the ideal efficiency of the column is considered.

Formulas for Steel Columns. A great many FORMULAS are used for calculating the strength of steel columns and struts, of the lengths usually employed in practice, but scarcely any two authorities agree upon the same one. These formulas may all be grouped into two general classes, those founded

* Elasticity and Resistance of the Materials of Engineering, by William H. Burr.

on RANKINE'S FORMULA * (11) and those founded on the STRAIGHT-LINE FORMULA (12). (See the following paragraphs.) In the different formulas different values are assigned to the ARBITRARY CONSTANTS. Previous to 1888 RANKINE'S or GORDON'S FORMULAS were almost universally used for all columns, although with more or less variation in the constants employed. About 1885 Professor Burr, after having conducted a series of tests upon full-size column-sections deduced what is now known as the STRAIGHT-LINE FORMULA. As this is easier of application than RANKINE'S FORMULA, it has gradually found favor with engineers, especially as the results differ but little from those obtained by the older formula.

Formulas Compared. Which one, of all the formulas in use, should be employed in calculating the safe load for columns is an open question, but the author, after careful deliberation, has decided to recommend RANKINE'S FORMULA for the following reasons. In the first place it is safe and conservative and if it errs at all, it is on the side of safety; and in the second place it has a wider application, as the values assigned to the arbitrary constants have been more generally agreed upon, whereas there is a greater variety in the values of the constants employed in the STRAIGHT-LINE FORMULA. Of course one is not free to choose when city laws compel the use of certain formulas. No tables of SAFE LOADS for columns, satisfying the requirements of all cities, could be compiled. The author has accordingly thought it best to insert the various tables of SAFE LOADS for different forms of columns as computed in the very latest handbooks although not necessarily based upon RANKINE'S FORMULA, and to insert Table XI, specially computed and giving the comparative SAFE LOADS IN POUNDS PER SQUARE INCH OF METAL-AREA for columns, as determined by seven different formulas. (See pages 493 to 495.)

Formulas Used in Building Codes. RANKINE'S FORMULA (called GORDON'S FORMULA in many codes) is specified in the building codes of the following cities: Philadelphia, Baltimore, Boston and Milwaukee, and is used in the Cambria handbook. The STRAIGHT-LINE FORMULA is specified in the building codes of New York City, Chicago, Minneapolis and Washington, and is used in the Carnegie and Bethlehem handbooks.

Formulas Used in Practice. The following formulas, in the opinion of the author, represent the best current practice. They are FORMULAS FOR SAFE LOADS, S, in pounds per square inch of cross-section, on steel columns and struts. In these formulas l is the LENGTH of the column in inches and r the LEAST RADIUS OF GYRATION of the cross-section. (See, also, Chapter X, pages 333, 344, etc.)

The SAFE LOAD, P, for any column is equal to S, obtained by one of the following formulas, multiplied by the SECTION-AREA of the column in square inches; or

$$P = AS \tag{10}$$

Rankine's formula, used in the Cambria handbook, is

$$S = \frac{12\,500}{1 + l^2/36\,000\,r^2} \tag{11}$$

The formula recommended by Professor Burr is

$$S = 10\,000 - 40\,l/r \tag{12}$$

The formula used by the American Bridge Company and Carnegie's Pocket Companion is

$$S = 19\,000 - 100\,l/r \tag{13}$$

with a maximum of 13 000 lb per sq in.

* Rankine's formula is sometimes referred to as Gordon's formula, but Gordon used the least lateral dimension or the diameter of the column instead of the least radius of gyration of the cross-section.

The formula used by the American Railway Engineering Association and the Chicago building code is

$$S = 16\,000 - 70\,l/r \tag{14}$$

with a maximum of 14 000 lb per sq in.

The formula used in the New York City and Washington, D. C., building codes, is

$$S = 15\,200 - 58\,l/r \tag{15}$$

The formulas used in the Catalogue of the Bethlehem Steel Company are

$$S = 16\,000 - 55\,l/r, \text{ for } l/r \text{ over } 55 \tag{16}$$

and $S = 13\,000$ lb per sq in, for l/r under 55

Fowler's slightly modified formula for steel struts in trusses is

$$S = 12\,500 - 50\,l/r \tag{17}$$

The value 50 in Fowler's formula is $41\frac{2}{3}$ when l is in inches, and 500 when l is in feet.

For a comparison of most of these formulas, see Table XI, pages 493 to 495 and the COMPARATIVE DIAGRAM OF FORMULAS, page 496.

14. Design of Steel Columns. Examples

Practical Use of Column-Formulas. Unlike the beam-formula the column-formulas in general use do not give a direct method of calculating the dimensions of a column that will support a given load, owing to the presence in the column-formula of two unknown quantities, A and r, which are dependent upon one another. Hence in designing columns, the section must be first assumed and then tested for the safe load P, or for the maximum unit fiber-stress S. This is an apparently roundabout method of designing columns, but unfortunately there seems to be no more direct way. When a column is to be selected or designed, its axial load P is given and also its length and the condition of its ends. A proper allowable unit stress, S, is assumed, suitable for the given material and for the conditions under which it is to be used, or in accordance with the requirements of the local building code; or the value of S is given in the specification according to which the column is to be designed. A cross-section is then selected in accordance with the principles explained on pages 467 to 469. For this assumed cross-section A and r are determined and then substituted in the formula, which is solved for P. If the assumed dimensions give a value for P that agrees with the actual load, they are correct. If, however, the resulting value of P is smaller than the actual load, the assumed size is too small, and it will be necessary to choose a larger size and solve again. If on the contrary, the actual load is less than the safe calculated load, a column with a smaller element of cross-section is assumed and a new value of P obtained. After a few trials a size that gives a satisfactory result for the required conditions will be found.

Examples Illustrating the Use of Column-Formulas and Tables. Since the column-tables in the last half of this chapter give the safe loads of the majority of column-sections of current practice, having determined which section it is most advisable to use under any given conditions, it is merely necessary to consult the tables and select the column of the required size to support the actual load.

Example 7. The following is an example showing the method of selecting BETHLEHEM ROLLED H COLUMNS for buildings.

Example Showing the Method of Selecting Bethlehem Rolled H Columns for Buildings

For illustration, the interior columns of an actual sixteen-story building are taken as an example. The story-heights and the loads on the columns are given in the following tabulation:

Stories	Heights of stories, ft	Loads on columns, tons	Safe loads, tons	H column-section required				
				Dimensions			Weights of sections, lb per lin ft	Section-numbers
				D, in	T, in	B, in		
16th	12	27	55.0	7⅞	7/16	8.00	31.5	H8
15th 14th	13 14	53 79	81.5	8⅜	11/16	8.12	48.0	H8
13th 12th	13 13	104 128	132.2	10⅜	13/16	10.12	71.0	H10
11th 10th	13 13	151 174	174.8	12¼	⅞	12.08	91.5	H12
9th 8th	13 13	197 219	219.1	14¼	15/16	14.08	114.5	H14
7th 6th	13 13	241 261	263.8	14⅝	1⅛	14.19	138.0	H14
5th 4th	13 13	281 301	310.1	15	15/16	14.31	162.0	H14
3d 2d	13 15	321 341	341.3	15¼	17/16	14.39	178.5	H14
1st Basement	17 12	363 395	403.5	15¾	111/16	14.54	211.0	H14

D is the depth of the column, T the thickness of the flanges and B the breadth of the flanges.

Columns for buildings are usually selected in lengths of two stories. By inspection of the tables of safe loads for H columns, it is found that no columns smaller than 14-in H sections have sufficient capacity for the lower stories. Where there is no limitation as to the size of the column, the column with the largest dimensions and having the required capacity will be the most economical. The unsupported length of a column should not exceed 150 radii of gyration, which is the limit of length for which safe loads are given in the tables. In the best practice the unsupported length of a column is frequently required not to exceed 120 or 125 times the least radius of gyration; various limits for l/r are indicated in the tables by zigzag lines. The safe loads given in the tables are for concentric or symmetric loading. When the loads are not centrally or symmetrically applied, the size of the column should be calculated by Formula (18), page 486.

Example 8. Suppose that in a 20-story office-building to be erected in Chicago, the load on each of the first-story columns, which are 16 feet in length, is 700 tons. What columns should be used?

Turning to Table XXI, page 515, giving the safe loads for Bethlehem 14-in H columns it is seen that a 14-in 287.5-lb column, the heaviest rolled, will support only 549.3 tons; this type of column, therefore, cannot be used. More-

over a casual inspection of the tables of safe loads for plate-and-angle and channel-columns shows that they are not suitable because of the thick flanges and web-plates required. Consequently the columns in the lower stories will probably have to be of the box type, with double or triple webs, as shown in Figs. 23 and 24. The upper columns, however, may be of the plate-and-angle or channel-type, whichever will be the more economical. The heaviest plate-and-angle column, without flange-plates (Table XXIV, page 522), composed of four 6 by 4 by ¾-in angles and one 12 by ½-in web, will support, for a length of 14 feet, the height of most of the upper stories, 469 000 lb; and a channel-column (Table XXVI, page 541) composed of two 12-in 30-lb channels and two 14 by ¾-in plates will support 502 000 lb. The former weighs 125 and the latter 131.4 lb per lin ft, so there is not much choice as far as economy of material is concerned. The channel-column, however, requires four rows of rivets while the plate-and-angle column requires only two rows, so this added expense of fabrication would have to be considered. Assuming, however, that the plate-and-angle type is more desirable, the next step is to design the individual columns.

The load upon each of the uppermost columns, which are 20 ft in length, is 70 000 lb. Turning to Table XXIV, page 518, it will be seen that a column composed of four 4 by 3 by ⅜-in angles and one 8 by ⅜-in web will support, for a length of 20 ft, 77 000 lb; but this load is below the lower zigzag line and hence the slenderness-ratio of the column exceeds 120. Assuming, for the purpose of illustration, that the limit of l/r is 120, a heavier section must be selected. On page 519 of Table XXIV, continued, it is seen that the lightest 20-ft column, for which l/r does not exceed the required ratio, is one composed of four 5 by 3½ by ⅜-in angles and one 10 by ⅜-in web, and that for a length of 20 ft it will support 121 000 lb, or 51 000 lb more than will come upon it.

Continuing the design of the columns, suppose that one in the 14th story, 14 ft in length, supports 175 tons, or 350 000 lb. From Table XXIV, page 522, it is found that a column composed of four 6 by 4 by ⅝-in angles and one 12 by ½-in web-plate, for a length of 14 ft, will carry 373 000 lb. In the table, the safe load is calculated by Formula (13), whereas the Chicago Building Code specifies Formula (14). Hence, as this building is to be erected in Chicago, the chosen column must be tested by the latter formula. Its A is 29.44 sq in and its least r, 2.65 in. To test it by the formula, $l = 14$ ft $\times$ 12 = 168 in, and l/r = 168 in/2.65 in = 63. Substituting in Formula (14), $S = 16\,000 - (70 \times 63) = 16\,000 - 4\,410 = 11\,590$ lb per sq in. From Formula (10), the safe load for the column, $P = AS$ = 29.44 sq in $\times$ 11 590 lb per sq in = 341 209 lb, which is less than the actual load. Therefore, the next heavier column, with angles 11/16 in thick, should be selected.

Example 9. In an office-building to be erected in Philadelphia, the use of the Bethlehem rolled-steel H columns has been decided upon. One of these columns, 15 ft in length, supports 170 000 lb, or 85 tons. What should be the size of this column?

According to Table XIX, page 508, giving the safe loads for Bethlehem columns, a 10-in 49-lb column, 15 ft in length, will carry 86.3 tons, an apparently safe load. Bethlehem-column loads, however, are calculated by the straight-line formula, whereas in Philadelphia, Rankine's (called Gordon's) formula is the standard. This formula with the arbitrary constants inserted is

$$S = \frac{16\,250}{1 + \frac{1}{11\,000}(l/r)^2}. \quad \text{(See Table XI, page 493.)}$$

From Table XIX, A = 14.37 sq in and the least r = 2.49 in; l is 15 ft or 180 in. l/r = 180 in/2.49 in = 72.3.

Substituting in the formula,

$$S = \frac{16\,250}{1 + \frac{1}{11\,000}(72.3)^2} = \frac{16\,250}{1 + 5\,227/11\,000} = \frac{16\,250}{16\,227/11\,000}$$

$$= \frac{16\,250 \times 11\,000}{16\,227} = \frac{178\,750\,000}{16\,227} = 11\,015 \text{ lb per sq in}$$

and from Formula (10), page 481,

$$P = AS = 14.37 \text{ sq in} \times 11\,015 \text{ lb per sq in} = 158\,285 \text{ lb or } 79.1 \text{ tons},$$

which is less than the tabular load. Hence the next heavier column, weighing 54 lb per sq ft, would have to be used.

Example 10. Figure 7, page 342, shows the cross-section of one of the basement-columns in the Bankers' Trust Company's Building, New York City. It is 20 ft in length and supports 2 230 tons. Is the column safe?

The first step is to find its least radius of gyration which is equal to $\sqrt{I/A}$. The least moment of inertia of this section was found to be 17 030. (See page 343.) The area is made up as follows:

FLANGES. The flanges are composed of six 27 by ¾-in plates and two 27 by 1¹⁄₁₆-in plates. The area of the cross-section of each 27 by ¾-in plate is 20.25 sq in and of the six plates, 121.50 sq in. The area of the section of each 27 by 1¹⁄₁₆-in plate is 18.56 sq in and of the two plates, 37.12 sq in. Hence the total sectional flange-area is 121.50 + 37.12 =	158.62 sq in
FLANGE-ANGLES. Each flange-angle is 6 by 6 by ¹⁵⁄₁₆ in. Its section-area is 10.38 sq in. Hence for the four, A = 10.38 × 4 =	41.52 sq in
OUTER WEB. The outer web-plates are each 18 by 1¹⁄₁₆ in. The area of each one is 12.375 sq in and of the eight	99.00 sq in
WEB. Each web-angle is 6 by 3½ by ¹⁵⁄₁₆ in with a section-area of 8.03 sq in; and for four angles the section-area is	32.12 sq in
WEB. The web is composed of two 18 by ⁹⁄₁₆-in plates, each with a section-area of 10.125 sq in. For two the area is	20.25 sq in
The area of the entire section, therefore, is	351.51 sq in

$$r^2 = I/A = 17\,030/351.5 = 48.5 \quad \text{and} \quad r = \sqrt{48.5} = 7 \text{ in}$$

$$l = 20 \text{ ft} = 240 \text{ in and } l/r = 240 \text{ in}/7 \text{ in} = 34.3$$

Substituting in the New York City building code Formula (15), page 482,

$$S = 15\,200 - 58 \times 34.3 = 15\,200 - 1\,989 = 13\,211 \text{ lb per sq in}$$

From Formula (10)

$$P = AS = 351.5 \text{ sq in} \times 13\,211 \text{ lb per sq in} = 4\,643\,666 \text{ lb, or } 2\,321 \text{ tons.}$$

Hence the column is perfectly safe.

15. Eccentric Loading of Steel Columns

General Principles. Where columns are used in tiers, one above another, the beams and girders which they support must necessarily rest upon brackets projecting or extending varying distances beyond the shell or section-areas or axes of the columns. Such connections cause BENDING MOMENTS in the columns. When equal loads are applied at equal distances on opposite sides of a column,

the bending moments caused by them in the column balance each other, and the CENTER OF STRESS may be considered as coinciding with the axis of the column. When, however, a load is applied on one side (Fig. 25) without a corresponding load on the opposite side, it is called an ECCENTRIC LOAD and the area of the cross-section of the column should be increased correspondingly. There is unfortunately no direct method by which this additional area can be determined. The usual method of procedure is to assume a section in excess of that required to support the total load and then compute the fiber-stress due to the combined balanced and eccentric loads. If this works out too large or too small another trial is made.

Formula for Eccentric Loads on Steel Columns. The following formula (compare with Fig. 25) is used to determine the combined fiber-stresses due to the concentric and eccentric loads:

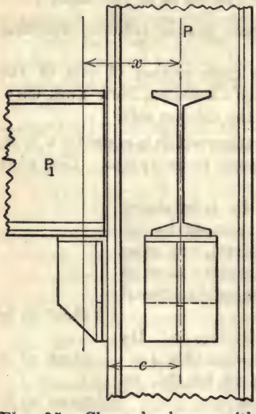

Fig. 25. Channel-column with Eccentric Load. Elevation

Let P = the concentric or balanced load in pounds,
P_1 = the eccentric load in pounds,
M = the bending moment due to the eccentric load in inch-pounds = P_1x,
x = the eccentricity of the load P_1 in inches. (See note below.)
I = the moment of inertia of the area of the cross-section of the column about an axis at right-angles to the direction of the bending,
c = the distance of the outermost fiber in the cross-section from the same axis,
A = the area of column-section in square inches and
S = the actual fiber-stress in pounds per square inch

Then

$$S = (P + P_1)/A + Mc/I \qquad (18)$$

Note. In measuring the ECCENTRICITY, the distance, x, is generally measured from the axis of the column to the center line or half-breadth line of the bracket or bearing.

Examples of Eccentric Loading of Steel Columns. The following examples illustrate the use of the formula and tables in determining the safe eccentric loads for steel columns.

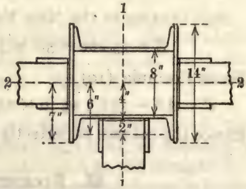

Fig. 26. Channel-column with Eccentric Load. Section

Example 11. The total load on the top of a column 32 ft in length is 194 000 lb, of which 30 000 lb come from the end of a girder. There is no corresponding load on the opposite side. (See Fig. 26.) It is proposed to use a channel-column. What is the size of the required column?

By referring to Table XXVI, page 539, it is seen that a column composed of two 12-in 20.5-lb channels and two 14 by ⅜-in plates will support, for a length of 32 ft, 227 000 lb, a somewhat greater load than will come on the column. For the section of this column, $I_{2-2} = 415$, $A = 22.56$ sq in, $r = 4.29$ in and $l/r =$

$384/4.29 = 89$. Substituting in Formula (11), page 481, to find the safe unit fiber-stress

$$S = \frac{12\,500}{1 + \frac{1}{36\,000}(l/r)^2} = \frac{12\,500}{1 + (89)^2/36\,000} = \frac{12\,500}{1 + 7\,921/36\,000} = \frac{12\,500}{43\,921/36\,000}$$

$$= \frac{12\,500 \times 36\,000}{43\,921} = \frac{450\,000\,000}{43\,921} = 10\,245 \text{ lb per sq in}$$

The actual stress in pounds per square inch of the column-section is found by Formula (18), $S = (P + P_1)/A + Mc/I$. $P = 164\,000$ lb, $P_1 = 30\,000$ lb, $A = 22.56$ sq in and $M = Px$ in-lb. x = the distance in inches from the axis 2–2 of the column to the outside of the web, plus the distance from the outside of the web to the center of the bracket. The former distance can be found from Table XXVI. It is 4 in. Let the distance from the outside of the web of the channel to the center of the bracket riveted to the web of the channel be 2 in, the projection of the bracket being 4 in; then x, the lever-arm of the moment of the load P_1, or the eccentricity, is 4 in + 2 in = 6 in. M, therefore, is P_1x or 30 000 lb × 6 in. c is 7 in, since the plates are 14 in wide. $I_{2-2} = 415$. Substituting in Formula (18)

$$S = \frac{164\,000 + 30\,000}{22.56} + \frac{30\,000 \times 6 \times 7}{415} = 8\,600 + 3\,036 = 11\,636 \text{ lb per sq in}$$

As this exceeds the safe unit fiber-stress of 10 245 lb per sq in, the column-section is too small.

For a second trial, consider a 12-in, 20.5-lb channel-column with 14 by ½-in plates. For this section, $I_{2-2} = 473$, $A = 26.06$ sq in, $r_{2-2} = 4.26$ in and $l/r = 384/4.26 = 90$.

$$S = \frac{12\,500}{1 + (90)^2/36\,000} = \frac{12\,500}{1 + 8\,100/36\,000} = \frac{12\,500}{44\,100/36\,000}$$

$$= \frac{12\,500 \times 36\,000}{44\,100} = 10\,204 \text{ lb per sq in.}$$

The actual stress from Formula (18), as before, is

$$S = \frac{164\,000 + 30\,000}{26.06} + \frac{30\,000 \times 6 \times 7}{473} = 7\,444 + 2\,664 = 10\,108 \text{ lb per sq in}$$

As this is less than the safe stress of 10 204 lb, the second selection is safe.

Example 12. A Bethlehem H column 14 ft long carries 90.56 tons, of which 15.52 tons are eccentric, being applied to the flange of the column as shown in Fig. 27, the distance from the outside of the flange to the center of the bearing being 2 in. What is the size of the column required?

Try a 12-in, 84.5-lb column, which, for a length of 14 ft, or 168 in, will carry 161.4 tons (Table XX). For this column, $A = 24.92$, $r_{2-2} = 3.03$, $I_{1-1} = 676.1$, $I_{2-2} = 228.5$ and l is 14 ft, or 168 in; hence $l/r = 168/3.03 = 55$. Substituting in Formula (15), assuming that that formula is specified, $S = 15\,200 - 58 \times 55 = 12\,010$ lb per sq in. Since the eccentric load causes bending in a direction at right-angles to the axis 1–1, Fig. 27, the bending moment due to the eccentric load is P_1, or 15.52 tons or 31 040 lb, multiplied by its lever arm x, which is the distance from the axis 1–1 to the outside of the flange plus the distance from this surface to the center of bearing. The former dimension, taken from the Bethlehem Catalogue, is 6¹⁄₁₆ in and the latter is 2 in; hence x = 8¹⁄₁₆ in or for convenience, 8 in. The distance, c, also, of the outermost fiber from the axis

1–1 is 6 1/16 in, which for convenience will be considered 6 in. I_{1-1} about the axis 1–1 is 676.1. Substituting in Formula (18), $S = (150\,080 + 31\,040)/24.92 + (31\,040 \times 8 \times 6)/676.1 = 7\,268 + 2\,204 = 9\,472$ lb per sq in. As this is far below the safe stress of 12 010 lb, the column selected is too large, and a smaller one, probably a 12-in 64.5-lb column would prove sufficient.

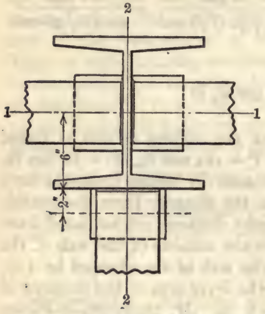

Fig. 27. Bethlehem H Column with Eccentric Load

Suppose, on the other hand, the eccentric load were applied to the web and the balanced loads to the flanges. The safe unit fiber-stress, as before, is 12 010 lb per sq in, for no matter how the loads are applied, the safe unit stress determined by reference to the least radius of gyration, r_{2-2}, should not be exceeded. Under the second condition of loading the eccentric load, also, will cause bending about this same axis 2–2; hence in Formula (18) the I for this axis, which is 228.5, must be used. $x = 2$ in $+ 0.25$ in $= 2.25$ in, 0.25 in being one-half the thickness of the web. (See the Bethlehem Catalogue.) Hence, from Formula (18), the actual unit fiber-stress is $S = (150080 + 31\,040)/24.92 + (31\,040 \times 6 \times 2.25)/228.5 = 7\,268 + 1\,835 = 9\,103$ lb per sq in.

16. Tables of Safe Loads for Steel Columns

Safe Loads per Square Inch of Metal-Area for Steel Columns and Struts. To lessen the labor of calculating the strength of steel columns and struts, of whatever shape, the author has computed Table XI, which gives SAFE VALUES of S for ratios of l/r varying from 30 to 120. For ratios of l/r which are not whole numbers, the values can be readily interpolated. The values in this table should correspond exactly with the results obtained by using the corresponding formulas.

Safe Loads for Steel-Pipe Columns. Tables XII and XIII give the SAFE LOADS for STEEL-PIPE COLUMNS. These loads are based upon the formula recommended by the New York City Building Code, $S = 15\,200 - 58\,l/r$. (See Steel-Pipe Columns, pages 469 to 474.)

Safe Loads for Channel and Angle-Struts. Tables XIV, XV and XVI give the SAFE LOADS for standard CHANNELS and ANGLES used as STRUTS. Only those sizes that are most commonly used are given. In Table XIV the SAFE LOADS for both the minimum and the maximum RADIUS OF GYRATION are given. If the strut is used also as a beam, or is stayed so that it cannot bend sidewise, the larger value may be taken; but if free to bend in either direction, then the smaller value should be taken. If the struts are subjected to a TRANSVERSE STRESS they should be computed as explained under the heading Strut-Beams, pages 571 and 572.

Safe Loads for Steel-Beam Columns, Bethlehem Columns, Lally Columns, Plate-and-Angle and Channel Columns. Tables XVII to XXVII, giving the SAFE LOADS for these columns, were not computed by the author, but by the different manufacturers; they are, however, believed to be perfectly safe, provided that an increase in area is made for ECCENTRIC LOADS.

Use of Table XI for Determining Safe Loads for Steel Columns. This table will be found of great assistance in calculating the strength of col-

umns and of struts and also in making calculations for eccentric loads. To use it to find the strength of a column, it is merely necessary to multiply the value corresponding to the SLENDERNESS-RATIO of the column, by the SECTION-AREA, the result being the SAFE LOAD the column can support. As an illustration of this, the column considered in Example 8 has a slenderness-ratio of 63 and a section-area of 29.44 sq in. Its strength is to be calculated by the Chicago Building Code formula, the results of which are tabulated in the sixth column of Table XI. From this the value of a slenderness-ratio of 63 is 11 590 lb per sq in. Therefore, by the rule stated above, the safe load is 11 590 lb per sq in $\times$ 29.44 sq in = 341 209 lb. In Example 10, the column in the Bankers' Trust Company Building has a slenderness-ratio of 34.3, and an area of 351.5 sq in. The value corresponding to 34, from column 5 of Table XI, is 13 228 and for 35 it is 13 170 lb per sq in; hence for 34.3 it would be about 13 211 lb per sq in. Accordingly, the safe load is 13 211 lb per sq in $\times$351.5 sq in = 4 643 666 lb.

Example 13. What is the safe resistance of a strut composed of two 5-in 9-lb channels, separated ½ in and free to bend in either direction, the length of the strut being 7 ft 6 in?

Solution. From Table XVIII, page 374, the least radius of gyration for this section is 1, hence $l/r = 90/1 = 90$. From the eighth column of Table XI, the value of S opposite 90 is 8 000 lb per sq in; the safe load, then, is equal to 8 000 lb per sq in, multiplied by the area of the two channels, 5.3 sq in, or 42 400 lb.

Example 14. What is the safe stress for a 7-in 15-lb **I** beam when used as a strut? It is 90 in in length and free to bend in either direction.

Solution. From Table IV, page 355, the least radius of gyration of this section is 0.78, and the area is 4.42 sq in. $l/r = 90/0.78 = 115.4$. From the eighth column of Table XI, the value opposite 115 is 6 750 and opposite 116 it is 6 700 lb per sq in; so for 115.4 it would be about 6 730 lb per sq in. The safe load, therefore, is 6 730 lb per sq in $\times$ 4.42 sq in = 29 746 lb.

By means of the tables and rules given in Chapter X the SECTION-AREA and LEAST RADIUS OF GYRATION of any standard section or any combination of sections may be found; and once these are determined the strength of a strut or column may be readily computed, as in the above examples.

Use of Table XI for Eccentric Loads for Steel Struts. As an illustration of its application to determine eccentric loads, refer again to Example 11. The value of l/r for this column is 89. The safe unit fiber-stress was found to be, by Formula (11), 10 245 lb per sq in. The practically identical result can be obtained by looking for the value opposite 89 in column 2 of Table XI. It is found to be 10 250 lb.

Proportion of Floor-Loads Borne by Columns. (See, also, pages 148 to 152.) In tall buildings it is customary to reduce the COLUMN-LOADS somewhat from the loads used in calculating the floor-beams. This is done on the theory that it is quite impossible for the entire floor-area of every story to be loaded to the maximum limit at the same time. For all buildings except warehouses it would seem, in general, to be good practice to design the columns to carry all the DEAD LOAD and 75% of the assumed LIVE LOAD. Of course city laws vary in these requirements. Thus, if in an office-building, the dead load, or weight of the floor-construction, is 80, and the live load 80 lb per sq ft, the load on the columns would be 80 + 60 = 140 lb per sq ft times the floor-area supported by the column. In some cases the reduction might be even greater, depending upon the live load assumed and the position of the column in the building, the reductions being greater in the lower than in the upper stories.

The Building Code of New York City specifies that for buildings exceeding five stories in height the COLUMN-LOADS shall be made up as follows: "For the roof and top floor the full live loads shall be used; for each succeeding lower floor it shall be permissible to reduce the live load by 5% until 50% of the live load is reached, when such reduced loads shall be used for all remaining floors." (For assumed loads for office-buildings, required by the building codes of several cities, see page 151.)

Column-Sheets. In a high building the COLUMN-LOADS vary to such an extent and are made up of so many elements, that to avoid omissions and errors it is necessary to make a TABULATED LIST of all the loads transferred through the columns to the footings. In a building of skeleton construction the COLUMN-LOADS include floor and roof-loads, wind-loads, spandrel and pier-loads, the weight of the columns themselves and their fire-proof covering, and in some cases special loads, such as tanks, vaults, safes and elevator-loads. In tabulating the FLOOR-LOADS it is advisable to separate the dead and live loads for convenience in proportioning the footings. (See, also, pages 148 to 160.) Formulas for computing the WIND-LOADS on columns are given in Chapter XXIX; these loads, also, are considered as live loads. ECCENTRIC LOADS should always be tabulated separately from the balanced column-loads. On page 491 is shown a form of COLUMN-SHEET which combines all ordinary requirements. The TOTAL LOAD for each story is the sum of all of the loads above. The SCHEDULE * on page 492 shows a very convenient form for column-lengths and column-parts.

* From Architectural Engineering, J. K. Freitag.

Form of Column-Sheet

Story	Character of loading	Column No. 1 Load on column, concentric	Column No. 1 Load on column, eccentric	Column 2
18th top	Roof and ceiling, dead load...... Roof and ceiling, live load....... Masonry piers.................. Spandrels, cornice, etc........... Elevators....................... Tanks........................... Column and casing.............. Wind-load......................			
	Total......................			
	Sectional area required..........	sq in	sq in	
17th	From column above.* Floor, dead load................. Floor, live load................. Masonry piers.................. Spandrels...................... Safes, vaults, etc................ Column and casing.............. Wind-load......................			
	Total......................			
	Sectional area required..........	sq in	sq in	
Basement	From column above.* Floor, dead load................. Floor, live load................. Masonry piers.................. Spandrels...................... Sidewalk....................... Column and casing.............. Wind-load			
	Total......................			
	Sectional area required..........	sq in	sq in	
Footings	Deduct (½) live load...........			
	Total footing-load...........			
	Area of footing required.........	sq ft		

* In bringing down the load from the column above, the eccentric loads may be added to the concentric loads and their sum placed in the first column.

Schedule of Column-Lengths and Parts

	Column No. 1		Column No. 2	
Roof-line				
Top of columns	1′ 6½″			
7th story	½″	Four angles 4″×3″×5/16″ One plate 7″×5/16″

Table XII.* Safe Loads in Tons of 2 000 Pounds for Standard Steel-Pipe Columns

Loads in tons of 2 000 pounds. Table based on New York City building laws. Formula used, $S = 15\,200 - 58\,l/r$, in which

S = allowable compressive stress for steel in pounds per square inch,
l = length of column in inches,
r = least radius of gyration in inches.

Loads above or to the left of the zigzag lines correspond to values of l/r greater than 120.

Table XIII.* Safe Loads in Tons of 2 000 Pounds for Extra-Strong Steel-Pipe Columns

Loads in tons of 2 000 pounds. Table based on New York City building laws. Formula used, $S = 15\,200 - 58\, l/r$, in which

S = allowable compressive stress for steel in pounds per square inch,
l = length of column in inches,
r = least radus of gyration in inches.

Loads above or to the left of the zigzag lines correspond to values of l/r greater than 120.

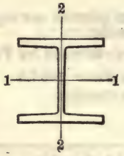
Weight, lb per lin ft	21	18	15	12¼	9¾	7½

Safe load-values above the upper heavy line are for ratios of l/r not over 60; those between the heavy lines for ratios up to 120 l/r; and those below the lower heavy line are for ratios not over 200 l/r

* From Pocket Companion, 1915 Edition, Carnegie Steel Company, Pittsburgh, Pa.

Table XVIII. Safe Loads in Tons of 2 000 Pounds for Bethlehem Rolled-Steel 8-Inch H Columns with Square Ends



Allowable stress in pounds per square inch:
13 000 for lengths under 55 radii;
16 000 − 55 l/r for lengths over 55 radii

CHAPTER XV

STRENGTH OF BEAMS AND BEAM GIRDERS. FRAMING AND CONNECTING STEEL BEAMS

By

CHARLES P. WARREN

ASSISTANT PROFESSOR OF ARCHITECTURE, COLUMBIA UNIVERSITY

1. General Principles of the Flexure of Beams

Definitions. A structural member placed in a generally horizontal position upon two or more supports or projecting from some other construction is called a BEAM. A GIRDER is a beam carrying smaller or secondary beams. A CANTILEVER BEAM is a beam supported at the middle, or having one end fixed, as in a wall, and the other end free; or it is the part of a beam which overhangs, or projects, beyond a support. A SIMPLE BEAM is one which rests upon two supports, one at each end. A CONTINUOUS BEAM rests upon more than two supports. The distance between the supports of a simple beam, or, when so specially designated from center to center of the bearings, is the SPAN. It is usually designated by l. The loads on beams are either UNIFORMLY DISTRIBUTED or CONCENTRATED. A uniformly distributed or UNIFORM load includes the weight of the beam itself and any load spread evenly over it, such as the weight of a wall. Uniform loads are estimated by their intensity per unit of length of the beam, in pounds per linear foot. A uniform load per linear foot is represented by w, and the total uniform load by wl or W. A concentrated load is a single applied weight, such as a column and its load, or the load from another beam, and is designated by P.

Stresses and Deformations. A load on a simple beam causes the fibers to bend or deflect, and eventually to break across, or in other words, a load induces TRANSVERSE OF FLEXURAL STRESSES in the fibers. Since it is impossible to bend or deflect a simple beam without causing a shortening of the fibers on the upper or concave side and an elongation of the fibers on the lower or convex side, a load on a beam causes COMPRESSION in the upper fibers and TENSION in the lower fibers, while between the two there is a neutral layer or surface of fibers which is unchanged in length and which is called the NEUTRAL SURFACE of the beam. In a cantilever beam the reverse is the case, the upper fibers being in tension and the lower ones in compression.

Laws Determined by Experiment. From experiments it has been found that the amount of elongation or shortening of any fiber is directly proportional to its distance from the neutral surface of a beam; hence, if the ELASTIC LIMIT is not exceeded, the stresses, also, are proportional to their distances from this neutral surface. The trace of the neutral surface on a cross-section of a beam is called the NEUTRAL AXIS of the cross-section. Within the elastic limit of a material the neutral surface passes through the CENTERS OF GRAVITY of the cross-sections of a beam for all materials.

Bending Moments and Resisting Moments.* To determine the strength of any beam to resist the effects of any load or series of loads, two things must

* See, also, Chapter IX, pages 324 and 325.

be determined: first, the moment or moments of the external destructive force or forces tending to bend and break the beam, which is called the MAXIMUM BENDING MOMENT; and, secondly, the moments of the combined resistances of all the fibers in the DANGEROUS SECTION of the beam to being broken, which, in their summation, are called the MOMENT OF RESISTANCE or the RESISTING MOMENT.

The Methods of Finding the Bending Moments for any load or series of loads are explained in Chapter IX. The moment of resistance is equal to the SECTION-MODULUS or SECTION-FACTOR, denoted by I/c, multiplied by the unit stress on the outermost fiber of the material, denoted by S, and it equals the bending moment.

Hence $$M = SI/c \tag{1}$$

This is known as the FLEXURE-FORMULA and it is the fundamental formula for designing beams. Formulas for finding the section-moduli of common shapes are given in Chapter X, and the values of I/c or the section-moduli of the standard rolled shapes, are given in the tables in the same chapter.

The Coefficient of Strength,* sometimes given in tables of steel beams, is the maximum distributed load that a beam of one foot span would support without producing a fiber-stress exceeding the safe limit, generally 16 000 lb per sq in. As the strength of a beam varies inversely as its span, the safe load for any span may be obtained by dividing this coefficient by the span in feet.

Factors of Safety. In order that a beam shall just be able to carry a load and not break, that condition of equilibrium must exist, in which the maximum bending moment in the beam is equal to the section-modulus multiplied by the ultimate strength of the material. In order that a beam may be abundantly SAFE to carry a given load, the product of the section-modulus by the ultimate strength of the material must be several times greater than the maximum bending moment; and the ratio which this product bears to the maximum bending moment, or which the BREAKING-LOAD bears to the SAFE LOAD, is known as the FACTOR OF SAFETY, that is,

$$\text{Factor of safety} = \frac{\text{ultimate strength}}{\text{working stress}}$$

Ultimate Strengths and Safe Fiber-Stresses. By the STRENGTH OF THE MATERIAL is meant a certain constant quantity which is determined by experiment, and which is known as the ULTIMATE BREAKING STRENGTH. This value is of course different for each material. Table I gives the values of this constant divided by the factor of safety, or in other words, the WORKING STRESS, for most of the materials used in building-construction. The section-moduli multiplied by these values will give the SAFE RESISTING MOMENTS for the beams. The values of S in Table I for steel are about one-fourth those of the breaking-loads; for cast iron, about one-sixth; for average specimens of wood, one-sixth; and for stone and concrete, one-tenth. The safe compressive strength of cast iron for the compression-side of beams is 16 000 lb per sq in, in the New York Building Code. This is considered too high by some engineers and the author recommends 10 000 lb per sq in. This value has been used in calculating the safe loads for cast-iron columns. (See Chapter XIV, page 461.) The safe loads for the steel shapes given in the tables in this chapter are all computed

* The values for coefficients of strength have been omitted from most of the tables, following the policy of some of the latest handbooks, as the safe loads for beams, for example, can be as readily determined from the data of the tables directly, as by the process of dividing such coefficients by the spans. See, however, pages 586 to 591 and 623 to 628.

on the value of 16 000 lb per sq in for S, but these full loads should be used with caution, and reduced when necessary to satisfy any unusual conditions. For riveted steel girders 14 000 lb per sq in is the value usually given to S.

Table I. Safe Unit Fiber-Stresses, S, for Flexure of Beams *

It is to be noted that these are average values, especially those for wood. For allowable higher stresses for timber, see also, notes on pages 628, 637 and 647.

Materials Wood unseasoned †	Values of S, lb per sq in	Materials Wood unseasoned †	Values of S, lb per sq in
Cast iron, tension-side	3 000	Redwood, California	750
Cast iron, compression-side	16 000	Short-leaf yellow pine	1 000
Wrought iron (rolled beams)	12 000	Spruce	700
Steel (rolled beams)	16 000	White oak	1 200
Steel (riveted girders, net flange-section)	14 000	White pine	700
Steel (pins, rivets and bolts)	20 000	Bluestone flagging (North River)	305
Cedar	700	Brick (common)	50
Chestnut	800	Brickwork (in cement)	30
Cypress	800	Granite (average)	180
Douglas fir	1 000	Limestone (average)	145
Elm	900	Marble (average)	125
Hemlock	600	Sandstone (average)	110
Locust	1 200	Slate (average)	400
Long-leaf yellow pine	1 200	Concrete (Portland) 1 : 2 : 4	30
Norway pine	800	Concrete (Portland) 1 : 2 : 5	20
		Concrete (natural) 1:2:4	16
		Concrete (natural) 1:2:5	10

* For a comparison of values given in different building laws see Table XVII, page 648, Chapter XVI. Compare, also, with Table XVI, page 647, Chapter XVI. For ultimate stresses for woods, see Tables XVIII and XIX, pages 650 and 651, Chapter XVI. For safe loads for unit beams, see Tables II and III, page 628, Chapter XVI.

† Add from 30 to 40% for seasoned, protected timber, used without impact.

Beams Unsymmetrically Loaded or of Irregular Cross-Section. There are certain loadings and cross-sections of beams that occur most frequently in building-construction, and for which tables have been worked out that give the safe loads directly; but for a beam unsymmetrically loaded, or for a beam of irregular cross-section, it is impossible to compute tables for strength, as in each case the values must be computed by determining either the section-modulus, I/c, required to resist the maximum bending moment, or the maximum bending moment that may be allowed for a given value of the section-modulus.

General Formulas for the Flexure of Beams.* The general formula for any beam in a state of flexure under any system of loading is

$$\text{Maximum bending moment in INCH-POUNDS} = \text{section-modulus} \times S \qquad (2)$$

or

$$M_{max} = SI/c \qquad (2)'$$

Also

$$\text{Section-modulus} = \frac{\text{maximum bending moment in in-lb}}{S} \qquad (3)$$

or

$$I/c = M_{max}/S \qquad (3)'$$

* See, also, Chapters IX, X and XVI.

If the bending moment is computed in FOOT-POUNDS, these formulas become

$$\text{Maximum bending moment} = \frac{\text{section-modulus} \times S}{12} \tag{4}$$

or

$$M_{max} = SI/12\,c \tag{4$'$}$$

and

$$\text{Section-modulus} = \frac{12 \times \text{maximum bending moment}}{S} \tag{5}$$

or

$$I/c = 12\,M_{max}/S \tag{5$'$}$$

By substituting for the bending moments their values in terms of the loads and the spans, the following formulas which apply to beams of any cross-section are readily deduced.

2. Formulas for Safe Loads for Beams for Different Conditions of Loading and Support

I/c = the section-modulus;
S = the safe unit fiber-stress in pounds per square inch;
W = the total uniform load in pounds;
P = the concentrated load in pounds;
l = the span in feet.

Values of I/c for the various shapes and sizes of structural-steel shapes are given in the tables of Chapter X.

Case I

Beam Fixed at One End and Loaded with a Concentrated Load P, Near the Free End (Fig. 1).

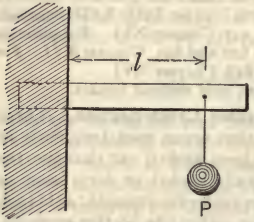

Fig. 1. Cantilever Beam. Load near Free End

From Formula (4)′,

$$M_{max} = SI/12\,c$$

From Case I, Chapter IX,

$$M_{max} = Pl$$

Hence

$$Pl = SI/12\,c$$

and the safe load in pounds is

$$P = SI/12\,cl \tag{6}$$

and the section-modulus is

$$I/c = 12\,Pl/S \tag{6$'$}$$

Example 1. A steel T bar is fixed at one end in a brick wall, and loaded at the other end with 600 lb, the distance l being 4 ft. What is the size of the bar required to support the load with safety? (In all examples the weights of the beams are neglected, unless particularly mentioned.)

Solution. Allowing 16 000 lb per sq in for the value of S, Formula (6)′ gives

$$I/c = (12 \times 600 \times 4)/16\,000 = 1.8$$

The next step is to ascertain what T bar has a section-modulus equal to 1.8. In Table XIV, page 369, the nearest section-modulus to this is 1.9, corresponding to a 3 by 4 by ½-in T bar.

For an **I** beam, by Table IV, page 355, I/c = 1.8, the same as for the T bar, and calls for a 3-in 6.5-lb **I** beam.

Case II

Beam Fixed at One End and Loaded with a Uniformly Distributed Load W (Fig. 2).

From Formula (4)′

$$M_{max} = SI/12\,c$$

From Case II, Chapter IX,

$$M_{max} = Wl/2$$

Hence

$$Wl/2 = SI/12\,c$$

and the safe load in pounds is

$$W = SI/6\,cl \qquad (7)$$

and

$$I/c = 6\,Wl/S \qquad (7)'$$

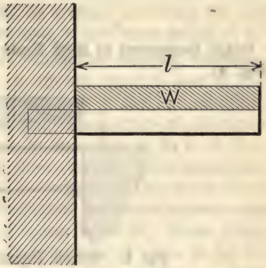

Fig. 2. Cantilever Beam. Distributed Load over Entire Span

Example 2. What is the size of a cantilever steel **I** beam required to carry a uniformly distributed load of 150 lb per ft over a length of 6 ft?

Solution. $W = 150 \times 6 = 900$ lb. Substituting in formula (7)′,

$$I/c = \frac{6 \times 900 \times 6}{16\,000} = 2.25$$

In Table IV, page 355, the nearest section-modulus to this is 1.9, which is that of a 3-in 7.5-lb beam, the heaviest of that depth. However, as the lightest 4-in beam, also, weighs 7.5 lb per ft it probably would be selected because of its greater stiffness, although its section-modulus is 3, still greater than required.

Case III

Beam Supported at Both Ends and Loaded with a Concentrated Load at the Middle (Fig. 3).

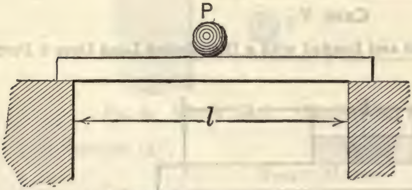

Fig. 3. Simple Beam. Load at Middle of Span

From Formula (4)′

$$M_{max} = SI/12\,c$$

From Case IV, Chapter IX,

$$M_{max} = Pl/4$$

Hence

$$Pl/4 = SI/12\,c$$

and the safe load in pounds is

$$P = SI/3\,cl \qquad (8)$$

and

$$I/c = 3\,Pl/S \qquad (8)'$$

Example 3. What steel **I** beam will safely support a concentrated load of 7 tons applied at the middle of a 15-ft span?

Solution. $P = 7$ tons $= 14\,000$ lb. Substituting in formula (8)′,

$$I/c = \frac{3 \times 14\,000 \times 15}{16\,000} = 39.3$$

Referring again to Table IV, page 355, it is seen that a 12-in 35-lb beam has

a section-modulus of 38, while a 12-in 40-lb beam, the next larger size, has a section-modulus of 44.8. The 35-lb beam, however, would undoubtedly be safe.

Case IV

Beam Supported at Both Ends and Loaded with a Uniformly Distributed Load (Fig. 4).

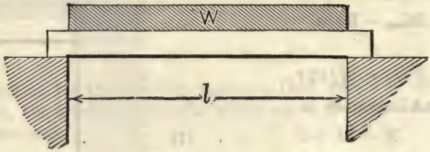

Fig. 4. Simple Beam. Distributed Load over Entire Span

From Formula (4)′

$$M_{max} = SI/12c$$

From Case V, Chapter IX,

$$M_{max} = Wl/8$$

Hence

$$Wl/8 = SI/12c$$

and the safe load in pounds is

$$W = 2SI/3cl \tag{9}$$

and

$$I/c = 3Wl/2S \tag{9'}$$

Example 4. What steel **I** beam will safely carry a uniformly distributed load of 1 000 lb per ft over a span of 25 ft?

Solution. $W = wl = 1\,000 \times 25 = 25\,000$ lb. Substituting in Formula (9)′,

$$I/c = \frac{3 \times 25\,000 \times 25}{2 \times 16\,000} = 58.6$$

From Table IV, page 354, the nearest section-modulus is 58.9, which is that of a 15-in 42-lb beam.

Case V

Beam Supported at Both Ends and Loaded with a Distributed Load Over a Part of the Span (Fig. 5).

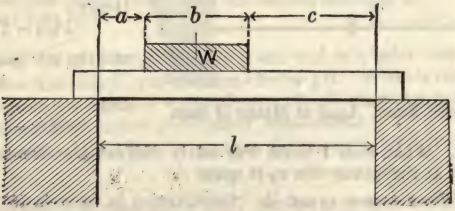

Fig. 5. Simple Beam. Distributed Load over Part of Span

In this case the load is generally given, and the problem is to determine the size of the required beam. This can be done accurately only by computing

the maximum bending moment as explained for Case VIII, Chapter IX, and substituting the value thus found in Formulas (3)′ or (5)′.

Example 5. What steel **I** beam will safely carry a uniformly distributed load of 1 200 lb per ft over part of the span, beginning at a point 5 ft from the left reaction and extending over a distance of 6 ft, the span of the beam being 18 ft?

Solution. The first step is to find the point of maximum bending moment, which is the point of no shear. Obviously the maximum shear is just at the right of the reaction nearest the load, which in this case is the left reaction. To find the left reaction (see Chapter IX, page 324) the center of moments is taken at the right reaction and the equation of moments is $R_1 \times 18$ ft − (1 200 lb × 6 ft) × 10 ft = 0. 18 R_1 = 72 000 and R_1 = 4 000 lb. The shear just at the right of R_1 is therefore +4 000 lb which, if the weight of the beam itself is not considered, remains unchanged for every section of the beam between the left reaction and the uniformly distributed load of 1 200 lb per ft. From there on in passing to the right, the shear is diminished at the rate of 1 200 lb per ft; and it becomes zero, therefore, at a point 4 000 lb/1 200 lb per ft = 3.3 ft to the right of the 5-ft point. Hence the point of no shear and consequently the point of maximum bending moment is at 5 ft + 3.3 ft, or 8.3 ft, from the left end. The equation for the maximum bending moment at this point is, therefore,

$$M_{max} = 4\,000 \text{ lb} \times 8.3 \text{ ft} - (1\,200 \text{ lb} \times 3.3 \text{ ft}) \times 3.3/2 \text{ ft}$$
$$= 33\,200 \text{ ft-lb} - 6\,574 \text{ ft-lb} = 26\,626 \text{ ft-lb, or } 319\,512 \text{ in-lb}$$

From Formula (3), I/c = 319 512 in-lb/16 000 lb per sq in = 20. From Table IV, page 355, the nearest section-modulus corresponding to this is 20.4, that of a 9-in 25-lb beam. A 10-in 25-lb beam, however, being stronger and stiffer, would probably be used. The 10-in 22 lb beam is what is termed a SUPPLEMENTARY BEAM. (See page 353.)

Case VI

Beam Supported at Both Ends and Loaded with a Concentrated Load, not at the Middle (Fig. 6).

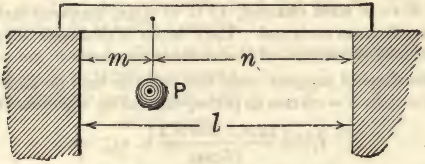

Fig. 6. Simple Beam. Concentrated Load at any Point

From Formula (4)′,

$$M_{max} = SI/12\,c$$

From Case VI, Chapter IX,

$$M_{max} = Pmn/l$$

Hence

$$Pmn/l = SI/12\,c$$

and the safe load in pounds is

$$P = SIl/12\,cmn \tag{10}$$

and

$$I/c = 12\,Pmn/lS \tag{10'}$$

m, *n* and *l* being in feet.

Example 6. A steel **I** beam 20 ft in span is to support a concentrated load of 24 000 lb at a distance of 6 ft from the left support. What must be the size and weight of the beam?

Solution. In this case $P = 24\,000$ lb, $l = 20$ ft, $m = 6$ ft, $n = 14$ ft and $S = 16\,000$ lb per sq in.

Then Formula (10)′ gives

$$I/c = \frac{12 \times 24\,000 \times 6 \times 14}{20 \times 16\,000} = 75.6$$

Table IV, page 354, the nearest value for the section-modulus I/c for axis 1–1 is above 75.6, or 81.2 for a 15-in 60-lb beam. An 18-in 55-lb beam having a section-modulus of 88.4 would be used, unless conditions fix the head-room, as it weighs 5 lb per ft less, and being deeper is consequently stiffer.

Case VII

Beam Supported at Both Ends and Loaded Symmetrically with Two Equal Concentrated Loads (Fig. 7).

Fig. 7. Simple Beam. Equal Concentrated Loads Symmetrically Placed

From Formula (4)′ and Case VII, Chapter IX, each of the safe loads in pounds is

$$P = SI/12\,cm \tag{11}$$

and

$$I/c = 12\,Pm/S \tag{11'}$$

Example 7. A 12-in steel channel, 12 ft in span, supports half the loads of two 10-in beams 4 ft from each end. Each beam is designed to carry 16 000 lb. What is the size and the weight of the channel required?

Solution. The channel supports only one-half the load on each beam; hence, $P = 8\,000$ lb, $m = 4$ ft, $S = 16\,000$ lb per sq in, and by Formula (11)′,

$$I/c = \frac{12 \times 8\,000 \times 4}{16\,000} = 24,$$

which is the section-modulus of a 12-in 25-lb channel. (See Table VIII, page 359.)

Weights of Beams in Flexure-Formulas. It will be noticed that in formulas (11) and (11)′ the span of the beam is not taken into account, and if the beam itself had no weight there would be no difference in the fiber-stresses no matter how far apart the loads P were placed. In reality, however, steel beams have considerable weight, and to be absolutely correct an example such as the one above should include the weight of the beam, which would, of course, be a uniformly distributed load. The maximum bending moment of the beam can be found graphically as explained on page 329, and the value of I/c computed by Formulas (3)′ or (5)′. Where, however, the loads are spaced so as to divide the beam into three equal parts, as in the last example, one-third of the weight of the beam may be added to P with sufficient accuracy. Thus, the

weight of the channel in the above example between the supports would be 25 lb × 12, or 300 lb, and P would be 8 100 lb, which would give a value for I/c of 24.1. The factor of safety in the loads allowed is generally large enough to offset the slight effect produced by the weight of the beam; but if the full load assumed is likely to be imposed on the beam, then allowance must be made for the weight of the beam itself.

Case VIII

Beam Supported at Both Ends and Loaded Symmetrically with Several Concentrated Loads (Fig. 8).

In this case it is necessary to compute the maximum bending moment in the beam and proportion the beam by Formulas (3)′ or (5)′.

Example 8. A steel-beam girder is to be designed to support a brick wall, 16 in thick and weighing 138 000 lb, over an opening 22 ft wide. The girder must also support the ends of four 10-in floor-beams spaced as in Fig. 8, each beam carrying 16 000 lb. What is the size and weight of the girder required?

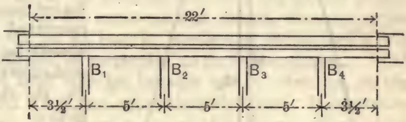

Fig. 8. Simple Beam. Several Concentrated Loads Symmetrically Placed

Solution. The first step is to make an allowance for the weight of the girder. The total load on the girder (neglecting the weight of the girder itself) = 138 000 lb + 4 × 8 000 lb (one-half the load on each beam) = 170 000 lb, or 85 tons. As this is much more than the heaviest single rolled beam will carry, it will be necessary to use a pair of beams and the load on each beam, therefore, will be 42.5 tons. Considering for the present the entire load as uniformly distributed, Table IV, page 577, shows that to support 42.5 tons, or 85 000 lb, over a span of 22 ft requires a 24-in 85-lb beam. The girder then will weigh between supports 2 × 85 × 22 = 3 740 lb, or about 4 000 lb. This added to the weight of the wall makes, for the total distributed load, 142 000 lb. The next step is to determine the maximum bending moment.

By the formulas given in Chapter IX the maximum bending moments for the various loads may be found as follows:
For the wall and girder (Case V, page 326),

$$M_{\max} = \frac{22 \times 142\,000}{8} = 390\,500 \text{ ft-lb}$$

For the beam B_1 (Case VI, page 327),

$$M_{1\,\max} = \frac{8\,000 \times 3\tfrac{1}{2} \times 18\tfrac{1}{2}}{22} = 23\,545 \text{ ft-lb}$$

For the beam B_2 (Case VI, page 327),

$$M_{2\,\max} = \frac{8\,000 \times 8\tfrac{1}{2} \times 13\tfrac{1}{2}}{22} = 41\,727 \text{ ft-lb}$$

The beams being spaced symmetrically from the middle of the span, the bending moments for B_3 and B_4 will be equal to those of B_2 and B_1 respectively. Plotting the bending moments to a scale, in the manner explained for Figs. 17 and 18, page 330, the diagram shown in Fig. 9 is obtained. The greatest bending moment is the ordinate M_x, which scales 486 500 ft-lb, or 5 838 000 in-lb.

Note. Since the loads are symmetrically placed, this ordinate is over the middle point of the girder, but it is drawn to one side in the figure in order not to confuse it with the ordinate M, the maximum bending moment for the uniformly distributed load. Substituting this value of M_x in formula (3)′,

$$I/c = \frac{5\,838\,000 \text{ in-lb}}{16\,000 \text{ lb per sq in}} = 365$$

the section-modulus for both beams, or 182.5 for one beam. From Table IV, page 354, it is found that a 24-in 90-lb beam has a section-modulus of 186.5, and two 90-lb beams will just answer. The assumption of a uniform distribution of such a loading over every foot of a girder usually results in the selection of lighter beams than are indicated by the second solution, in which each concentrated load is considered as really concentrated at a point. The two beams should be securely bolted together with separators near each connection of beams B_1, B_2, B_3, B_4, and at each end of the girder.

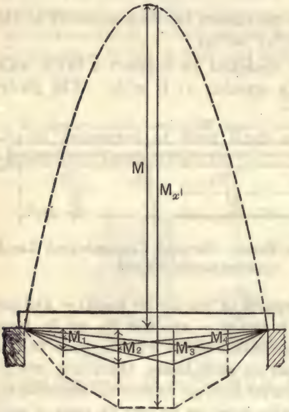

Fig. 9. Bending-moment Diagram for Beam Shown in Fig. 8.

A DOUBLE-BEAM GIRDER, however, is not considered the best kind of girder to use under this condition of loading, as it is not good construction nor economical of material. As a general rule BEAM GIRDERS should be used only when the loads can be applied to the upper flanges of both beams. Transferring a load directly to the web of one beam, even though it is connected with the other beam by means of separators, does not insure as equal distribution of the loading. The author, therefore, recommends in this case a RIVETED BEAM GIRDER or a RIVETED PLATE GIRDER. The method above indicated applies to any method of loading, the only difference in the calculation being in the determination of the maximum bending moments.

Inclined Beams. The strength of beams inclined to the horizontal may be computed, with sufficient accuracy for most purposes, by using the formulas given for horizontal beams, and taking the HORIZONTAL PROJECTIONS of the beams as the spans.

3. Steel Beams and Girders *

Materials Used for Beams. Practically the only materials used in structural work for beams, at the present day, are wood, steel and reinforced concrete. As wooden beams are always rectangular in cross-section, the general formulas used in this chapter can be much simplified by substituting for I/c its value in terms of the breadth and depth of the beam. Formulas for wooden beams will therefore be found in Chapter XVI. Cast iron, also, is occasionally used for beams or lintels, but as this material is much stronger in resisting compression than tension, the beam must be of a special shape in order to use the material to advantage. The strength of cast-iron beams is therefore considered under

* For the deflection of steel beams, see Chapter XVIII.

a special heading in Chapter XVI. Formulas for reinforced-concrete beams are given in Chapter XXIV, pages 935 to 940.

Forms of Steel Beams. Since 1893, steel beams have superseded wrought-iron beams, and the latter are now never used. Any shape of rolled steel may be used as a beam, but the **I** shape is the most economical, as it possesses the greatest resistance for a given weight of metal. Next to the **I** beam, in economy, is the channel, then the deck beam; angles and tees are the least economical of all shapes. The following values show the safe loads per pound of steel, for the various shapes, for a 10-ft span; the same ratio would hold for other spans.

10-in **I** beam	10-in channel	10-in deck-beam	4 by 6-in angle	4 by 5-in tee
104	94.6	83.0	28.7	21.6

The Deepest Beams, the Strongest, Stiffest and Most Economical. The STRENGTH of a wooden or steel beam of rectangular cross-section varies as the SQUARE OF THE DEPTH, directly as the breadth and inversely as the length, and the STIFFNESS varies directly as the CUBE OF THE DEPTH, directly as the breadth and inversely as the cube of its length; hence the deeper beam will have the greater strength and stiffness in proportion to its sectional area. With **I** beams these relations do not hold strictly, because of the variation in the forms of the cross-sections, but they are approximately true. It therefore follows that, for any given span, it is more economical in floors, where other conditions will permit, to use deep beams spaced farther apart or to use one deep beam in place of two shallower beams. Thus if a distributed load of 39 tons is to be supported over a span of 16 ft, one 20-in 65-lb beam, two 15-in 42-lb beams, or three 12-in 40-lb beams, could be used; but the 20-in beam would weigh only 1 105 lb, allowing for 6-in bearings, as compared with 1 428 lb for the 15-in beams and 2 040 lb for the 12-in beams, and the bolts and separators would be saved.

Light and Heavy Steel Beams. LIGHT BEAMS are more economical than heavy beams OF THE SAME DEPTH, except when the span is so short that the safe load is governed by the resistance of the web to buckling, in which case the HEAVY BEAMS are the more economical.

Maximum Safe Loads for Steel Beams. All loaded beams are, in general, subject to three kinds of stresses. The most destructive are generally those due to the BENDING MOMENTS, and have already been considered. The second kinds are those which tend to SHEAR a beam, or to make one part slide on the other vertically. (See paragraph on Shearing-Stresses in Steel Beams and Girders, page 567.) These stresses, however, seldom need to be considered except in the case of riveted girders and short beams with very thick webs. The third kind of stress is that which tends to cause the web of a beam to BUCKLE; and in a steel beam over a span very short in proportion to the depth of the beam, the resistance of the web to buckling generally determines the maximum load that the beam, without stiffeners on the web, will support. (See, also, pages 182, 183 and 567.)

Safe Loads for Steel Beams.* To save time in calculating, tables of safe loads for structural and supplementary beams and channels used as beams under conditions of transverse loading, have been prepared, which give the UNIFORMLY DISTRIBUTED SAFE LOADS in thousands of pounds for spans customary

* Part of the matter of the following paragraphs relating to steel **I** beams has been adapted, by permission, from the Pocket Companion, 1915 Edition, Carnegie Steel Company, Pittsburgh, Pa.

in building-construction. They are based upon an extreme FIBER-STRESS of 16 000 lb per sq in on the fibers farthest from the neutral surface of the beam.

The Tables of Safe Loads for Angles and Tees, pages 586 to 591, give the values at the same fiber-stress on spans of one foot, from which the safe load for any span-length may be obtained by direct division, and also the values for those spans at which the allowed safe load will produce a deflection of 1/360 of the span-length. The loads in all cases include the weight of the beam, which should be deducted in order to arrive at the net load which the beam will support. For several concentrated loads or for a combination of distributed and concentrated loads it will be necessary to use the methods previously explained under Case VIII, page 563.

Use of Tables for Concentrated Loads. To use any of the following tables for CONCENTRATED LOADS, find the equivalent distributed load by multiplying the concentrated load by the factor given in Table IV, page 632, and then use the beam having a safe load equal to the load thus found.

In addition to the conversion-factors in that table the following, also, will be found convenient:

For two equal loads applied at one-third the span from each end, multiply one load by 2⅔.

For two equal loads applied at one-fourth the span from each end multiply one load by 2.

For a beam fixed at one end, and loaded at the other, multiply by 8.

For a beam fixed at one end, and uniformly loaded over the entire length, multiply by 4.

Unusual Conditions of Loading of Beams.* It is assumed in all cases that the loads are applied normal to the axis 1–1 as shown in the tables of the properties of sections in Chapter X, and that the beam deflects vertically in the PLANE OF BENDING ONLY. If the conditions of loading involve the introduction of forces outside this plane of loading, the allowable safe loads must be determined from the general theory of flexure in accordance with the mode of application of the load and its character. This applies particularly to UNSYMMETRICAL SECTIONS, such as angles, which should be used under those conditions of loading where the section can deflect vertically only, being rigidly secured against LATERAL DEFLECTION or twisting throughout the entire span. In all such cases of eccentric loading, the actual safe loads would be considerably lower than the tabulated safe loads, which have been based upon the most favorable conditions of loading.

Vertical Deflection of Steel Beams.* In the case of beams intended to carry plastered ceilings, experience indicates that the VERTICAL DEFLECTION, to avoid cracking the plaster, should be limited to not more than 1/360 of the span-length. This SPAN-LIMIT for steel beams is approximately, in feet, twice the depth in inches and is indicated in the tables by the lower, broken, horizontal lines. Beams intended for such purposes should not be used for greater spans unless the allowable tabular safe load exceeds the actual load to be supported. As the dead load of a floor is supported by the floor-beams before the plaster is applied, only the deflection due to the live load really needs to be considered. The vertical deflection of beams is explained in Chapter XVIII.

Lateral Deflection of Steel Beams.* The tabular safe loads are based upon the assumption that the compression-flanges of the various sections are

* Part of the matter of this paragraph has been adapted, by permission, from the Pocket Companion, 1915 Edition, Carnegie Steel Company, Pittsburgh, Pa.

secured at proper intervals, against LATERAL DEFLECTION, by the use of tie-rods or by other means. The LATERAL UNBRACED LENGTH of steel beams and girders should not exceed forty times the width of the compression-flanges. When the unbraced length exceeds ten times the width, the tabular safe loads should be reduced. An explanation of the method of reducing the tabular loads when the unsupported length exceeds ten times the flange-width is given in Chapter XVIII, page 670.

Shearing-Stresses in Steel Beams and Girders.* The safe-load tables for beams and channels are computed solely with reference to SAFE UNIT STRESSES DUE TO FLEXURE, and the safe loads uniformly distributed on the spans given will not cause average SHEARING-STRESSES in the web greater than the 10 000 lb per sq in, the average SAFE WORKING STRENGTH of steel in SHEAR. When, however, beams are loaded with heavy loads concentrated near the supports, or when beams of short span are loaded with uniformly distributed loads to their full carrying capacity as regards flexure, the bending moments may be small in comparison with the reactions at the supports, and the beams may fail along the neutral surface as a result of LONGITUDINAL SHEARING-STRESSES, or they may BUCKLE as a result of the combined longitudinal and vertical web-stresses. On such spans the safe shearing or buckling strength of the web rather than the resistance of the flanges to bending-stresses may limit the carrying capacity of the beam.

Buckling Values of Beam-Webs.* The VERTICAL SHEARING-STRESSES or the vertical compressive components of the web-stresses may under some conditions exceed the safe resistance of the beam to BUCKLING, and there remains the possibility that a web or web-plate, which is amply secure against the safe allowed shear of 10 000 lb per sq in, will not be of sufficient strength when considered as a column. In such cases provision must be made for security against BUCKLING either by stiffeners or by an increased thickness of the web or web-plate. (For the determining conditions for web-buckling of steel beams in grillages, based on direct compression, see page 183.)

Conditions of Web-Buckling of Steel Beams. There are two conditions of WEB-BUCKLING (see, also, foot-note for paragraphs relating to Tables II and III).

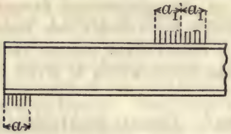
(1) The part of the beam bearing on the support is subject to DIRECT COMPRESSION, and the web over this part must be capable of resisting it. If this area is too small the end of the beam will fail, as a column, causing the web to BUCKLE. It is therefore necessary to calculate the required length of the bearing.

(2) The beam throughout its length between the supports, or in case of a cantilever beam, from its end to the support, is subject to SHEAR. It is generally supposed that the shear develops stresses of TENSION and COMPRESSION in the web; that these stresses act at right-angles to each other in the plane of the web and at an angle of 45° with the neutral surface of the beam; and that these DIAGONAL STRESSES are equal in magnitude or intensity to the VERTICAL SHEAR at any point. It is the COMPRESSIVE STRESS that tends to BUCKLE the web.

Formulas for Safe Buckling Resistance of Steel Beams.* In regard to the first condition of buckling a series of experiments has been made on beams of various depths and web-thicknesses to arrive at a basis for a simpler method of computation to use in the investigation of the safe BUCKLING RESISTANCE of

* Part of the matter of this paragraph has been adapted, by permission, from the Pocket Companion, 1915 Edition, Carnegie Steel Company, Pittsburgh, Pa.

beams with unsupported webs, and from these experiments the following formulas * have been deduced:



Safe end-reaction $R = S_b \times t\left(a + \frac{d}{4}\right)$

Safe interior load $P = 2\,S_b \times t\left(a_1 + \frac{d}{4}\right)$

In these formulas, R is the end-reaction, P the concentrated load, t the web-thickness, d the depth of the beam, a_1 half the distance over which the concentrated load is applied and a the whole distance over which the end-reaction is applied; while S_b is the SAFE RESISTANCE OF THE WEB TO BUCKLING, in pounds per square inch, by the straight-line formula

$$S_b = 19\,000 - 100\,d/2\,r$$

$d/2 = l$ in the column-formula †. The first formula is general and applies to any condition of loading. The second formula covers the case of a single load concentrated at the middle of a span; it can be extended to cover a system of concentrated loads provided the sum of the distances a_1 is not less than a.

Tables II ‡ and III ‡ give for beams and channels with unsupported webs:

* These formulas, in order to satisfy the first condition, are used in the Pocket Companion, 1915 Edition, Carnegie Steel Company, Pittsburgh, Pa.

† This is the column-formula used by the American Bridge Company and in Carnegie's Pocket Companion, S being the allowable COMPRESSIVE UNIT STRESS in pounds per square inch within the usual limits of l/r. See Formula (13), page 481.

‡ In regard to the shearing of steel beams, allowable web-shears, etc., the value, for example (see Example 15, this chapter, and on pages 182 and 183 of Chapter II), of 42 000 lb per sq in for a 12-in, 31½-lb **I** beam, given in Table II, page 575, taken from Carnegie's Pocket Companion, is based on the allowed direct shear without including the condition of web-crippling. That is, the 42 000 lb is determined by taking the area of the web, $0.35 \times 12 = 4.2$ sq in and multiplying it by 10 000 lb per sq in, which is the value there used for the safe unit shearing-stress.

The beam is therefore calculated as being good for 42 000 lb SHEAR, but it is necessary to make a further investigation to ascertain whether the stresses due to shear will cause the web of the beam to buckle. As stated in the paragraph on page 567, on the Buckling Values of Beam-Webs there are two conditions of web-buckling or web-crippling.

In the case of a plate girder the end-stiffeners provide for the first condition, and the intermediate stiffeners for the second condition. The web itself may then be counted on for its full shearing value. In the case of beams, however, it is not generally economical to use stiffeners, so that the web alone must meet every condition.

The Carnegie Pocket Companion gives a formula, reproduced in the preceding paragraph, and gives the derived lengths of bearings in Tables II and III, to satisfy the first condition. Some of the formulas used in the manufacturers' handbooks, for maximum safe shear based on web-buckling for the second condition, are as follows:

Passaic Steel Company, $V = \dfrac{10\,000\,dt}{1 + \dfrac{h^2}{3\,000\,t^2}}$

Cambria Steel Company, $V = \dfrac{12\,000\,dt}{1 + \dfrac{h^2}{1\,500\,t^2}}$

Bethlehem Steel Company, $V = \dfrac{12\,000\,dt}{1 + \dfrac{h^2}{3\,000\,t^2}}$

(1) " The allowed WEB-RESISTANCE S_b, in pounds per square inch, computed from this compression-formula. (See, also, page 183.)

(2) " The distance a, or the distance over which the end-reaction must be distributed when the shearing-stress V in the web is the maximum allowable stress of 10 000 lb per sq in.

(3) " The allowable END-REACTION R, when a is taken at 3½ in, which is the usual length of beam actually resting on the 4-in angles ordinarily used in building-construction for beam-seats.

(4) " The allowable SHEAR V, on the gross area of the cross-section of the beam or channel-webs, at 10 000 lb per sq in."

In regard to the second condition of WEB-BUCKLING, the MAXIMUM ALLOWABLE SHEAR may be calculated by the formula,

$$V = \frac{12\,000\,dt}{1 + \dfrac{h^2}{1\,500\,t^2}}$$

in which V = the maximum safe web-shear in pounds; d = the depth of the beam; t = the thickness of the web; and h = the height between the flange-fillets. (See Example 15, this chapter and also example on pages 182 and 183.)

" In addition to these data which have to do with the MAXIMUM LOADS on beams and channels as computed from the WEB-RESISTANCE, Tables II and III give, also, the MAXIMUM BENDING MOMENTS in foot-pounds, obtained by the multiplication of the SECTION-MODULUS of each section by the allowed FIBER-STRESS of 16 000 lb per sq in and the division of the product by 12 in order to reduce to a foot-pound basis. These maximum bending moments may be used on inspection instead of the table of properties to ascertain the proper size of a section to be used in any particular instance."

in all of which V = the maximum safe web-shear in pounds; d = the depth of the beam; t = the thickness of web; and h = the distance between the flange-fillets.

It is to be noted that the length of the element in compression on the 45° line is $h\sqrt{2}$, and that the square of this length is $2\,h^2$. It is this value, $2\,h^2$, that is substituted for l^2 in the column-formula used by the Cambria Steel Company in deducing its formula for shear based on web-buckling. The tensile stress, however, tends to keep the compressive stress from buckling the web, and for this reason the Passaic and Bethlehem engineers take the more liberal value of $3\,000\,t^2$ instead of $1\,500\,t^2$. The Passaic Steel Company, however, used the more conservative unit value of 10 000 lb, reduced, instead of the 12 000 lb used by the others. The Passaic and Cambria formulas give about the same results, a 12-in, 31½-lb **I** beam by the former having a safe shear of 33 352 lb and by the latter, 33 188 lb.

The Passaic Steel Company is no longer in existence and their handbook is out of print. The Bethlehem Steel Company's handbook has tables for Bethlehem shapes only. If, in any case, no table of maximum shears of beams, based on web-crippling, is at hand, it is suggested that the values may be determined from the formula,

$$V = \frac{12\,000\,dt}{1 + \dfrac{h^2}{1\,500\,t^2}}$$

in which, as before, V = the maximum safe web-shear in pounds; d = the depth of the beam; t = the thickness of the web; and h = the distance between the flange-fillets. For the beam mentioned and used in Example 15, page 571, in this chapter and in the example on pages 182 and 183, $d = 12$ in, $t = 0.35$ in, $h = 9.762$ in, $t^2 = 0.1225$, $h^2 = 95.296644$ and $V = 33\,188$ lb. This formula is recommended as being the most conservative, although there is not a great difference in the results, and the formula of the former Passaic Steel Company is retained elsewhere in Kidder's Pocket-Book. See, for example, page 686 and Table III of Chapter XX. Editor-in-chief.

Table VII is a table computed by Mr. Kidder, giving the strength of small rectangular steel channels or grooved steel. These are often used for supporting metal lath in suspended ceilings, and the table will be found useful in determining the size to use for any given span and spacing.

4. Tables of Safe Loads for Steel Beams and Girders. Examples

Example 9. Direct Bending from a Uniformly Distributed Load. As an illustration of the use of these tables let it be required to determine the proper size and weight of an **I** beam to carry safely a uniformly distributed load of 34 000 lb over a span of 20 ft, the weight of the beam not being included.

Solution. From Table IV, page 579, a 15-in 50-lb beam will carry 34 400 lb. The weight of this beam is 50 lb × 20 ft = 1 000 lb, making a total load to be supported of 35 000 lb. This is so little in excess of the safe load that the excess need not be considered. Had the difference been more, however, the next heavier beam should be used.

Example 10. Direct Bending from a Concentrated Load. To illustrate the use of the tables to determine the size and weight of beams required to carry concentrated loads, Examples 10 and 11 are given. What **I** beam, 15 ft in span, will safely support 8 000 lb, concentrated at a point 5 ft from the left support?

Solution. The distance 5 ft is one-third of the span, and the conversion-factor for this (Table IV, page 632) is 1.78. The equivalent uniformly distributed load, therefore, is 8 000 × 1.78 = 14 240 lb, and from Table IV, page 581, a 9-in 25-lb **I** beam will carry 14 500 lb for a span of 15 ft, and will just answer the purpose.

Example 11. Direct Bending from Two Equal Concentrated Loads. What **I** beam, 15 ft in span, will safely support two equal concentrated loads of 6 000 lb each, applied 5 ft from each end?

Solution. The distance 5 ft is one-third the span, but the multiplier in this case is 2⅔ (page 632). Hence, the equivalent uniformly distributed load is 6 000 × 2⅔ = 16 000 lb and the beam required (Table IV, page 580) is a 10-in 25-lb, **I** beam which will carry 17 400 lb. The same result is obtained by using Formula (11)′, page 562. This formula is, $I/c = 12\,Pm/S$. Substituting, $I/c = 12 \times 6\,000 \times 5/16\,000 = 22.5$. The nearest section-modulus to this is 24.4, that of a 10-in 25-lb **I** beam.

Example 12. Maximum Bending Moment from a Distributed Load Over Part of the Span. The beam in Example 5, Case V, page 561, has a maximum bending moment of 26 626 ft-lb. What beam is required?

Solution. The nearest bending moment to this in the first column of Table II, page 575, is 27 240 ft-lb, which corresponds to a 9-in 25-lb **I** beam.

Example 13. Allowable Web-Shear.* The maximum shear in the beam of Example 12 is just at the right of the left reaction or bearing, and equals 4 000 lb. Is the beam safe for shear?

Solution. From Table II, page 575, in the column for V, the allowable web-shear for a 9-in 25-lb beam is 36 540 lb. Hence, the beam is safe if web-buckling is not taken into account.

Example 14. Shear.* It is required to determine the maximum load which a 9-in 25-lb **I** beam can support without exceeding the safe web-resistance of the section.

* See paragraphs and foot-note relating to buckling of beam-webs, pages 567 to 569.

Solution. From Table IV, page 581, the maximum load for this beam, given in small figures above the heavy, horizontal lines, is 73 100 lb.

Example 15. Safe Buckling Resistance. See, also, paragraphs and foot-note relating to buckling of beam-webs on pages 567 to 569 and also example on pages 182 and 183. According to Table II, page 575, the allowable web-shear for a 12-in, 31.5-lb **I** beam is 42 000 lb. Will this shear cause the web of the beam to buckle?

Solution. The web-shear is determined by multiplying the area of the web, that is, 0.35 in × 12 in = 4.2 sq in, by 10 000 lb per sq in, the safe unit shearing-stress. The maximum shear which will not cause the web to fail by buckling may be found by the formula given on page 569 for the second condition of web-buckling.

$$V = \frac{12\,000\,dt}{1 + \dfrac{h^2}{1\,500\,t^2}}$$

From the dimensions of structural beams (see Carnegie's Pocket Companion, Seventeenth Edition, page 64) the thickness t of the web of a 12-in, 31.5-lb **I** beam is 0.35 in, the depth of the beam is $d = 12$ in and h, the distance between flange-fillets, is 9.762 in. Substituting these values in the formula,

$$V = \frac{12\,000 \times 12 \times 0.35}{1 + \dfrac{9.762^2}{1\,500 \times 0.35^2}} = \frac{50\,400}{1 + \dfrac{95.296644}{1\,500 \times 0.1225}} = \frac{50\,400}{1 + \dfrac{95.296644}{183.75}} = \frac{50\,400}{\dfrac{279.046644}{183.75}}$$

$$= \frac{50\,400 \times 183.75}{279.046644} = \frac{9\,261\,000}{279.046644} = 33\,188, \text{ or about } 33\,190 \text{ lb}$$

As this is less than the allowable web-shear of 42 000 lb given in the tables, if account is to be taken of the web-buckling from the second condition mentioned in the preceding pages, a larger or heavier beam should be used or the loads reduced, so that the maximum shear will not exceed 33 190 lb. (For determining conditions for web-buckling of steel beams in grillages, based on direct compression, see page 183.)

Example 16. Safe End-Reactions for Web-Buckling. In Example 8, page 563, the two 24-in 90-lb **I** beams carry 170 000 lb + (4 000 lb, the weight of the beams) = 174 000, lb or 87 000 lb for each beam. Assuming that they rest upon 4-in brackets riveted to columns at each end of the span, are the end-reactions excessive?

Solution. Since the loading is symmetrical, each reaction for each beam is one-half the total load on each beam, or 43 500 lb. From the last column in Table II, page 574, the maximum end-reaction R, for a 24-in 90-lb beam, is 74 410 lb. Hence, the beam is safe as far as the compression from the end-reactions is concerned.

Strut-Beams. It is not considered good construction to subject a strut to a transverse loading, causing a certain amount of flexure in and thus adding to the compressive stress. Conditions often exist, however, where practical considerations make it desirable to use a strut as a beam, also, as in the top chord or in the principals of a truss. To determine the size of a member in a case of this kind the following method should be used:

(1) Find the section-modulus I/c, for the member for the transverse load by Formulas (2)′ to (11)′, using 12 000 lb per sq in as the value of S, and find the area of the cross-section of a steel shape corresponding to the value of I/c thus found. See note at end of Example 17.

(2) Find the section-area required to resist the compressive stress, by dividing that stress by the value opposite l/r in column VIII of Table XI, page 493.

(3) Add together the two areas and use for the required member a piece or pieces of material having a section-area next larger than the total area found.

Example 17. Strut-Beam. Combined Bending and Compression. The principal rafter in a truss, 8 ft 6 in long between joints, supports the end of a purlin at the middle of the span. The weight from the purlin is 2 800 lb and the compressive stress in the rafter 30 000 lb. It is proposed to use a pair of angles for the rafter, set with the long legs vertical and ½ in apart. What are the dimensions of the angles, the strut being braced laterally?

Solution. (1) By Formula (8)′, $I/c = 3 \times 2\,800 \times 8.5/12\,000 = 5.95$ for the pair of angles, or 2.98 for each angle. (See note at end of this example.) From Table XI, page 363, the nearest value to this with reference to the axis 1–1 is 3.0, the section-modulus for a 5 by 3½ by ½-in angle. The section-area of one angle is 4 sq in and of two angles, 8 sq in.

(1) From Table XVI, page 371, the least r for a pair of 5 by 3½ by ½-in angles, which would be about the axis 1–1, since the strut is braced laterally, is about 1.58 (between 1.55 and 1.61). Then the slenderness-ratio l/r = 8 ft 6 in/1.58 in = 102 in/1.58 in = 64.5. From column VIII, Table XI, page 493, S = 9 250 lb per sq in. Hence, 30 000 lb/9 250 lb per sq in = 3.24 sq in, approximately.

(3) The section-area required, therefore, is 8 + 3.24 = 11.24 sq in, which, from Table XI, page 363, is about equivalent to that of two 5 by 4 by 11/16-in angles. As the section-area in both calculations exceeds that actually required, no allowance for the weight of the angles need be made.

Note. Because of the increase in the tendency of the strut to deflect, caused by the combined stresses of flexure and compression, lower values of S are used than in the cases of simple flexure, or of simple compression.

Tie-Beams. Steel beams subject to combined tensile and transverse stresses should be calculated in a way similar to that explained above for strut-beams. The section necessary to resist the transverse stress should be found first, then the section-area necessary to resist the tensile stress, and the two added together.

Example 18. Tie-Beam. Combined Bending and Tension. One span of a tie-beam, 10 ft between joints, supports a load of 6 000 lb at the middle, and at the same time is under a tensile stress of 84 000 lb. It is proposed to use two steel channels for the tie-beam. What size and weight are required for the channels?

Solution. A load of 6 000 lb applied at the middle of a beam has the same effect as a load of 12 000 lb uniformly distributed, or 6 000 lb for each channel. From Table V, page 584, a 7-in, 9.75-lb channel will be required, its section-area (Table VIII, page 359) being 2.85 sq in. The additional area required to resist the tensile stress is 84 000 lb/16 000 lb per sq in = 5.25 sq in, or 2.63 for each channel. The total area for each channel, therefore, should be 2.85 + 2.63 = 5.48 sq in. A 7-in, 19.75-lb channel has a section-area of 5.81 sq in, and an 8-in, 18.75-lb channel has a section-area of 5.5 sq in. Either one will be sufficient, but the 8-in channel will probably be more economical, as it weighs 1 lb per ft less.

Example 19. Channel, Set Flatwise. What is the size of the channel, set flatwise, required to support a uniformly distributed load of 180 lb per ft over a span of 10 ft, or 120 in?

Solution. $W = 180 \times 10 = 1\,800$ lb. From Case V, page 326, $M_{max} = Wl/8 = 1\,800 \times 120/8 = 27\,000$ in-lb. From Formula (3)′, page 557, $I/c = M/S =$

$27\,000/16\,000 = 1.7$. From Table VIII, page 359, the I/c about the axis 2–2 corresponding to this is that of a 12-in, 20.5-lb channel.

Example 20. Rectangular Steel Bar with Long Side Vertical. In a suspended, plastered ceiling it is proposed to use 2 by 3/8-in steel bars, 4 ft or 48 in long, to carry the plaster. What is the safe load each bar will support, if set with the long side vertical?

Solution. From Table I, page 346, the I for a 2 by 3/8-in bar is 0.250. $c =$ one-half the depth = 1 in. $I/c = 0.250/1 = 0.250$. Also, from Formula (2)′, page 557, $M_{max} = SI/c$. Substituting, $M_{max} = 16\,000 \times 0.250 = 4\,000$ in-lb. But, from Case V, page 326, $M_{max} = Wl/8$, and hence, $4\,000 = W \times 48/8 = 6\,W$, and $W = 4\,000/6 = 666$ lb.

Loads above the upper heavy lines will cause maximum allowable shears in webs. See, also, paragraphs in text and foot-note with same, page 567, relating to web-buckling in beams

Loads below the lower broken lines will cause excessive deflections

* From Pocket Companion, 1915 Edition, Carnegie Steel Company, Pittsburgh, Pa.

Loads above the upper heavy lines will cause maximum allowable shears in webs. See, also, paragraphs in text and foot-note with same, page 567, relating to web-buckling in beams

Loads below the lower broken lines will cause excessive deflections

* From Pocket Companion, 1915 Edition, Carnegie Steel Company, Pittsburgh, Pa.

Bethlehem I Beams.* BETHLEHEM I BEAMS from 8 to 24 in in depth, inclusive, have the same strength, or section-modulus, as STANDARD BEAMS of the same depth. Bethlehem beams, due to the proportions of the sections, weigh generally 10% less than standard beams of the same depth and strength. For example (Table VI, page 357), a Bethlehem 15-in I beam, weighing 54 lb per ft, has a section-modulus of 81.3. The corresponding standard section (Table IV, page 354) is a 15-in I beam weighing 60 lb per ft, with a section-modulus of 81.2. Therefore, for equal strength, the Bethlehem beam weighs 6 lb per ft less than the standard beam, or a saving of 10% in weight. Similar comparisons with other sizes of the standard beams previously rolled by the mills of this country show that the Bethlehem I beams afford an equal carrying capacity, but with practically 10% less weight of metal.

Thickness of Webs and Flanges. It is claimed that the WEBS of standard beams are much thicker than required for a scientifially proportioned section. It is impossible to reduce the WEB-THICKNESS in the ordinary mill, but with the Grey Mill webs of the desired thickness can be produced. By adding to the FLANGES part of the metal thus saved, the strength of the beam is maintained, thereby affording a lighter section of the same strength. The WIDE FLANGES give increased lateral stiffness, which commends the use of such beams in many cases, where the NARROW FLANGES and lack of sufficient lateral rigidity prevent the use of ordinary standard beams.

Depth and Weight of Bethlehem Beams. Formerly the heaviest beams rolled in this country were 24 in deep, weighed 115 lb per ft, and had a section-modulus of 246.3. Whenever greater strength was required, a riveted girder was necessary. Bethlehem beams are rolled to a maximum depth of 30 in, weigh 200 lb per ft, and have a section-modulus of 610, or two and one-half times the strength of the largest beam previously rolled. The opportunity for using ROLLED BEAMS instead of BUILT-UP RIVETED GIRDERS is, therefore, greatly increased. These rolled beams and girders afford a saving in WEIGHT OF METAL and also a large economy in COST OF FABRICATION, as they do not require the punching, assembling and riveting necessary for building a riveted girder.

Bethlehem Girder Beams.* BETHLEHEM GIRDER BEAMS, from 8 to 24 in in depth, inclusive, have a strength, or section-modulus, equal to that of two minimum-weight STANDARD I BEAMS of the same depth. The girder beam, however, weighs generally 12½% less than the combined weight of the two standard beams, not considering the saving in weight of separators needed for assembling the standard beams into a girder. For example, a Bethlehem 15-in girder beam, weighing 73 lb per ft has a section-modulus of 117.8 (Table VII, page 358). Two standard 15-in I beams, each weighing 42 lb per ft, have together a like section-modulus of 117.8 (Table IV, page 354). Thus, for equal depth and strength, the girder beam weighs 11 lb per ft less than the two standard beams. This is a saving of 13% in weight, not including separators, which would add at least 2½ lb per ft more to the weight of the assembled girder. In this case a total saving of 16% in weight is afforded by the Bethlehem girder beam, besides the saving in the cost of assembling the standard beams into a girder.

Safe Uniformly Distributed Loads for Bethlehem I Beams and Girder Beams. Tables XII * and XIII,* pages 594 to 602, give the SAFE UNIFORMLY DISTRIBUTED LOADS in tons of 2 000 lb, on Bethlehem girder beams and I beams for a maximum fiber-stress of 16 000 lb per sq in. The tabular loads include

* Adapted by permission from the Catalogue of Bethlehem Structural Shapes, Bethlehem Steel Company, South Bethlehem, Pa.

the weight of the beam, which must be deducted to obtain the net load a beam will support. Safe loads for INTERMEDIATE or HEAVIER WEIGHTS of beams can be obtained from the separate COLUMN OF CORRECTIONS, given for each size. This last column of the table states the increase in safe load for each pound of increase in weight per foot of beam. If the load is CONCENTRATED AT THE MIDDLE OF THE SPAN, the safe load is one-half the safe uniformly distributed load for the same span. The SAFE LOADS ON SHORT SPANS may be limited by the shearing strength of the web, instead of by the maximum fiber-stress allowed in the flanges. This limit is indicated in the tables by the heavy horizontal lines. The loads given above these lines are greater than the SAFE CRIPPLING or BUCKLING STRENGTH OF THE WEB, and must not be used unless the webs are stiffened.* In such cases it will generally be advisable to select a heavier beam with a thicker web. To use these tables for other spans, or for other distribution of the loading, see explanation, page 566. To use these tables for beams not secured against YIELDING LATERALLY, see Lateral Deflection, pages 566 and 670.

* See paragraphs and accompanying foot-note, page 567, relating to web-buckling of beams.

Safe loads given include weight of beam. Maximum fiber-stress, 16 000 lb per sq in

Loads given above the heavy lines are greater than safe loads for web-crippling. See paragraphs and accompanying foot-note, page 567, relating to web-buckling of beams

Safe loads given below the lower, broken line cause deflections exceeding 1/360 of the span

The section-numbers are given for convenience in identification and ordering

Safe loads given include weight of beam. Maximum fiber-stress, 16 000 lb per sq in

Safe loads given below the broken lines cause deflections exceeding 1/360 of the span

The section-numbers are given for convenience in identification and ordering

Riveted Single-Beam and Double-Beam Girders.* Where a SINGLE ROLLED BEAM is insufficient to carry a load, the required capacity may be secured by fabrication in various ways. Two BEAMS can be used, connected by bolts and separators. The total strength of these is twice that of the SINGLE BEAM of the same depth and weight. Care should be taken, however, to see that the loads are apportioned to them equally, and where it is necessary for the beams to act as a unit, the separators should consist of plates and angles and not be made of cast iron. If the loading is not uniformly distributed over the two beams, the strength of each must be computed separately. The use of a SINGLE-BEAM GIRDER with plates at top and bottom to sustain a given load is often more economical in material than the use of TWO BEAMS connected by bolts and separators. The beam girders in Table XIV, pages 605–6, have about twice the carrying capacity of the single beams of which they are built.

Tables XIV and XV give the SAFE LOADS for the SINGLE AND DOUBLE-BEAM GIRDERS commonly used. The values given in the tables are founded upon the moments of inertia of the various sections, deductions being made for the rivet-holes in both flanges. In Table XIV, taken by permission from Carnegie's Pocket Companion, the safe loads are based upon a fiber-stress for flange-bending of 16 000 lb per sq in, and in Table XV, retained from the former edition of Kidder's Pocket-Book, upon a fiber-stress of 13 000 lb per sq in. For other fiber-stresses, as 14 000 or 15 000 lb per sq in, the safe loads in Tables XIV or XV may be decreased or increased by PROPORTION as the LOADS vary as the FIBER-STRESSES.†

* For tables of riveted plate girders, see Chapter XX.

† The editors decided to retain Table XV for the safe uniformly distributed loads for riveted steel-beam box girders, based upon a bending fiber-stress of 13 000 lb per sq in. To use this table for fiber-stresses of 14 000, 15 000 or 16 000 lb per sq in, divide the tabular loads by 13 and multiply the quotients by 14, 15 or 16, respectively, for the safe load at the required fiber-stress. In regard to Table XV, Mr. Kidder said, in the preceding editions of this pocket-book, "in order to amply compensate for the deterioration of the metal around the rivet-holes from punching, and also because these girders are more often used to support permanent loads, such as brick or stone walls, the maximum fiber-stress [for riveted double-beam girders] was limited to 13 000 lb per sq in, although it is but right to state that most of the latest handbooks of the steel-manufacturers give tables of safe loads for such girders based upon a fiber-stress of 15 000 lb per sq in. The author advises that for loads of masonry, which usually come very close to the estimated loads, and which are constantly applied, the girders be not loaded beyond the values given in the following tables (that is, based upon 13 000 lb per sq in), while for ordinary floor-loads, which seldom reach the estimated loads, an addition of ⅙th may be added to the values given in the tables."

Girders fabricated of single steel **I** beams and plates riveted to the upper and lower flanges, as shown in Table XIV, are not often used to support masonry walls, because of their relatively narrow flange-width and lack of lateral stiffness. In case they are used to support masonry walls and are not thoroughly braced laterally, it is recommended that the safe loads be reduced as explained, from those given in Table XIV, to agree with a fiber-stress of 13 000 or 14 000 lb per sq in, according to the span, bracing, character of loading, etc. It is recommended, also, that for girders fabricated of two steel **I** beams and plates riveted to the flanges, as shown in Table XV, and carrying masonry walls, the safe loads, given in this table and computed for a fiber-stress of 13 000 lb per sq in, be used, or, if increased, that the fiber-stress be taken not greater than 14 000 lb per sq in.

Recent handbooks have contained tables of safe uniformly distributed loads for fabricated steel girders computed from safe unit fiber-stresses, in pounds per square inch, for flange-bending as follows. For RIVETED SINGLE-BEAM GIRDERS: Carnegie Steel Company, 1903 Edition, no tables; Carnegie, 1915 Edition, 16 000, based upon the section-modulus of the gross area of the cross-section; Cambria Steel Company, 1911 Edition, no tables; (former) Passaic Steel Company, 1903 Edition, no tables; Kidder's Pocket-Book, previous editions, no tables. For RIVETED DOUBLE-BEAM GIRDERS: Car-

Example 21. A 13-in brick wall, 15 ft high, is to be built over an opening of 24 ft. What is the size of the double-beam girder required?

Solution. Assuming 25 ft as the distance, center to center of bearings and 121 lb per cu ft as the weight of brickwork, the weight of the wall is $25 \times 15 \times 121 =$ 45 375 lb, or about 22.68 tons. From Table XV, page 610, a girder composed of two 12-in steel beams, each weighing 31.5 lb per ft, and two 14 by ½-in flange-plates will carry safely, for a span of 25 ft, a uniformly distributed load of 23.23 tons, including its own weight. Deducting the latter, 1.42 tons, given in the next column, the result is 21.81 tons for the safe net load, which is 0.87 ton less than required. From the following column of the table it is seen that by increasing the thickness of the flange-plates 1/16 in it is safe to add 1.52 tons to the allowable load. This will more than make up the difference. Hence the required DOUBLE-BEAM GIRDER will be composed of two 12-in 31.5-lb beams, and two 14 by 9/16-in steel flange-plates.

A SINGLE-BEAM GIRDER (according to Table XIV, page 606), composed of one 15-in 42-lb **I** beam and two 8 by ½-in flange-plates will carry, at 16 000 lb per sq ft, 49 000 lb over a span of 25 ft, and as it is lighter, weighing but 69.2 lb per ft to the others 113.6 lb, it would be more economical. The DOUBLE-BEAM GIRDER is, however, more suitable in this particular case, as the 13-in wall should have a wider bearing than 8 in, and, also, the safe load should be decreased from the tabular load to correspond to a fiber-stress of 13 000 or 14 000 lb per sq in because of the nature of the loading, the long span, etc., or, what amounts to the same thing, the strength of the girder should be increased to correspond to the decreased fiber-stress. (See foot-note, page 603.) A 49 000-lb load at 16 000 lb per sq in fiber-stress corresponds to a $49\,000 \times {}^{16}/_{13} = 60\,307$-lb load at 13 000 fiber-stress, as far as selecting a corresponding girder from table is concerned. A SINGLE-BEAM GIRDER (Table XIV) composed of one 15-in 60-lb **I** beam and two 9 by ⅝-in flange-plates will carry 68 000 lb and weighs only 98.3 lb per ft. Therefore, as far as strength is concerned, to suit the conditions of loading, this would be the proper SINGLE-BEAM GIRDER to use, and it would also be cheaper than the DOUBLE-BEAM GIRDER determined by Table XV; but the width of bearing for the 13-in wall is still only 9 in compared to 14 in with the DOUBLE-BEAM GIRDER.

negie, 1903, 15 000, 13/16-in rivet-holes deducted; Carnegie, 1915, no tables; Cambria, 15 000, 13/16-in rivet-holes deducted; Passaic, 15 000, 13/16 or 14/16-in rivet-holes deducted; Kidder, previous and new editions, 13 000, 14/16-in rivet-holes deducted. For RIVETED SINGLE-WEB, PLATE-AND-ANGLE GIRDERS (see Chapter XX): Carnegie, 1903, 15 000, 13/16-in rivet-holes deducted; Carnegie, 1915, 16 000, based upon section-modulus of the gross area of cross-section; Cambria, 15 000, 13/16 or 14/16-in rivet-holes deducted; Passaic, 15 000, 13/16 or 14/16-in rivet-holes deducted; Kidder, previous editions, 12 000 and 13 000 for flanges, 13/16 or 14/16-in rivet-holes deducted (also contained the Passaic tables). For RIVETED MULTIPLE-WEB, PLATE-AND-ANGLE GIRDERS (see Chapter XX): Carnegie, 1903, 15 000, 13/16-in rivet-holes deducted; Carnegie, 1915, 16 000, based upon section-modulus of the gross area of cross-section (the elements, only, of these girders, and not the loads, are given); Cambria, no tables; Passaic, 15 000, 13/16 or 14/16-in rivet-holes deducted; Kidder, previous editions, same as for single-web plate-and-angle girders.

For fabricated steel girders the building laws (1913) of New York City and Chicago respectively specify fiber-stresses of 14 000 and 15 000 lb per sq in computed for the net flange-sections.

The revised edition of Kidder's Pocket-Book uses, by permission, the Carnegie, 1915, tables for all but the riveted double-beam girders, for which the old Kidder tables are retained. The limiting conditions of use are fully explained in the text and foot-notes. Editor-in-chief.

39	11.37	2.13	0.66	10.06	1.84	0.67	0.10

The above values based on a maximum fiber-stress of 13 000 lb per sq in, rivet-holes in both flanges deducted. See paragraph on Riveted Single-Beam and Double-Beam Girders, page 603, and the foot-note for same regarding fiber-stresses. Weights of girders correspond to lengths, center to center of bearings.

Beams Supporting Brick Walls. In calculating the size of a girder to support a brick wall, the structure of the wall should be carefully considered. If the wall is without openings and does not support floor-beams, only that part of the wall included within the dotted lines, Fig. 10, need be considered as being supported by the girder. The beams in that case, however, should be made very STIFF, so as to have little DEFLECTION. If there are several openings above the girder, and especially if there is a pier over the middle part of it, as shown in Fig. 11, then the manner in which the loading is distributed should be carefully considered. In a case of this kind, only the dead weight included between the dotted lines AA and BB should be considered as coming upon the girder, and proper allowance made for the CONCENTRATION of the greater part of the load at or near the middle. If, however, the lower windows are two-thirds their total width, or more, above the girder, then it is more reasonable to suppose that the wall included between the lines CC rests upon the girder, and also to consider that this load is UNIFORMLY DISTRIBUTED over it. When beams extend under the entire length of a wall which is more than 16 or 18 ft long, the weight of the entire wall rather than the weight of a triangular part of it should be taken as coming upon the beams; for, if they should bend, the wall would settle, and might push out the supports and cause the whole structure to fall. (See, also, page 318.)

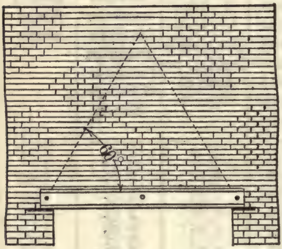

Fig. 10. Triangular Loading of Beams under Brick Walls

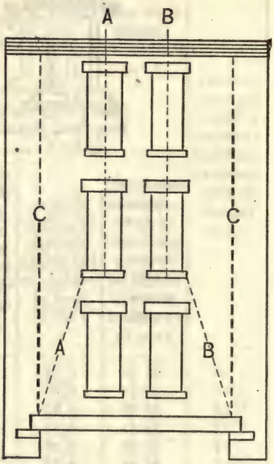

Fig. 11. Loading of Beams under Walls with Openings

5. Framing and Connecting Steel Beams and Girders

Standard Separators. When beams are used to support walls, or as girders to carry floor-beams, they are often placed side by side; and should in such cases be connected by means of BOLTS and cast-iron SEPARATORS fitting closely between the flanges of the beams. The office of these separators is, in a measure, to hold in position the compression-flanges of the beams by preventing SIDE DEFLECTION OF BUCKLING, and also to unite the beams so as to cause them to act in unison as regards VERTICAL DEFLECTION. Separators should be provided at the supports, at points where heavy concentrated loads are imposed, and at regular intervals of from 5 to 6 ft between. The illustrations, dimensions, etc., given in Table XVI, are for the STANDARD SEPARATORS in common use.

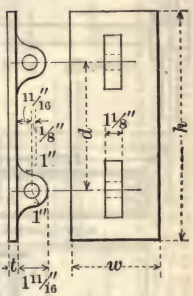
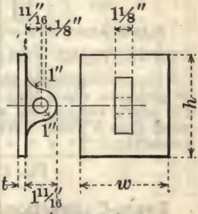
Diagrams



⅞″ cored holes

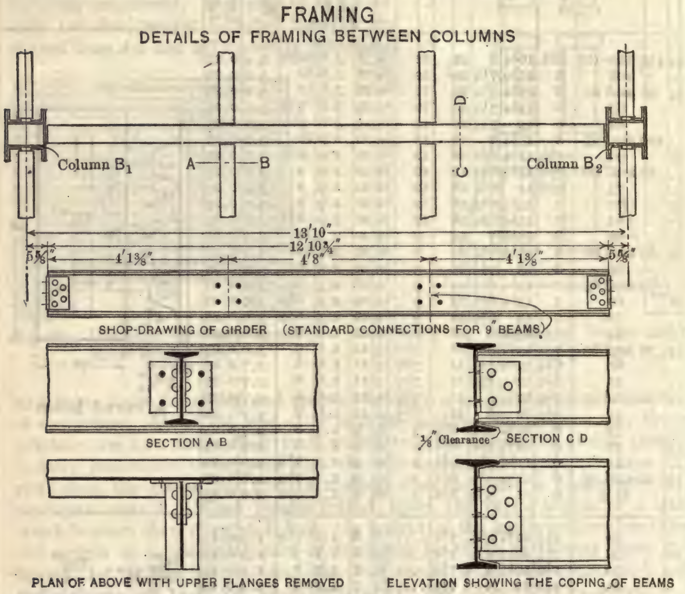


⅞″ cored hole

For 5-in, 4-in and 3-in beams, use 1-in gas-pipes, 3¼, 3 and 2¾-in long, respectively

* From Pocket Companion, 1915 Edition, Carnegie Steel Company, Pittsburgh, Pa.

Gas-Pipe Separators. Separators formed of pieces of GAS-PIPE, cut to the desired lengths and slipped over the bolts are often used by contractors. (See bottom of Table XVI.) Such separators permit the beams to act independently of each other, and should not be used in any place where one beam is liable to receive a greater load than the other; and as this condition exists in almost every case where two or more beams are used together, it follows that "cast-iron separators, made to fit the space between the beams," should be specified in almost every instance. As noted in Table XVI, gas-pipe may sometimes be used for 5, 4 and 3-in beams. Separators with two bolts should be used for beams 12 in or more in depth. For 12-in beams one bolt is sometimes used when the load is light; for beams under 12 in in depth one bolt is sufficient.



CONNECTIONS FOR BEAMS AND GIRDERS

"Connection-angles shall in no case be less in thickness than the web of the beam or girder to which they are fastened, nor shall the width be less than ⅓ the depth of the beam, except that no angle-knee shall be less than 2½″ wide nor required to be more than 6″ wide. Web-angles, the full depth of the web, must be used for all girder-connections."

Fig. 12. Framing of Steel I Beams and Girders

Beam-Connections. Steel beams and channels are FRAMED together by means of short pieces of angles, which are usually riveted to the floor-beam or tail-beam and bolted to the girder. The angles are always used in pairs, one on each side of the beam. If the floor-beam is framed flush, either with the top or bottom of the girder, or if two beams of the same height are framed together, the end of the beam supported should be COPED, or cut to fit the shape of the girder or supporting beam. The maximum clearance-space allowed between the end

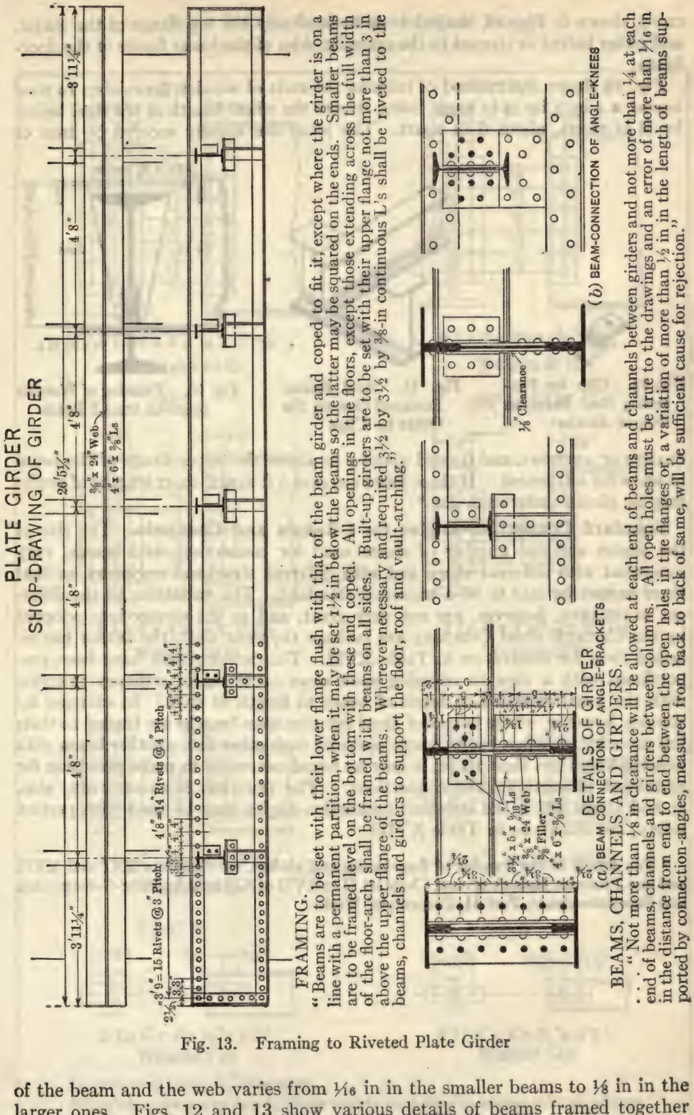


Fig. 13. Framing to Riveted Plate Girder

of the beam and the web varies from 1/16 in in the smaller beams to ⅛ in in the larger ones. Figs. 12 and 13 show various details of beams framed together and also to girders. When a floor-beam rests on top of another beam or girder, as in Fig. 15, the beam should be secured by means of a pair of wrought-iron

CLIPS, shown in Fig. 14, shaped so as to fit closely the top flange of the girder, and either bolted or riveted to the opposite sides of the lower flange of the floor-beam.

Fig. 16 shows one method of framing the ends of wooden floor-joists to steel beams, a 4 by 3 by ⅜-in angle being riveted the whole length of the steel beam, by ¾-in rivets, about 6 in apart. The joists are usually secured by iron or

Fig. 14. Clip for Fastening Steel Beam on Top of Another

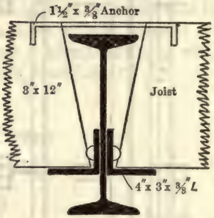

Fig. 16. Framing of Wooden Joists to Steel I Beam

CLAMPS OT ANCHORS, and framed about 1 in above the upper flange of the beam to allow for settlement. If these joists are over 3 ft apart, short lengths of angles may be placed under each one.*

Standard Connection-Angles for I Beams and Channels. The size of the angles and the number of rivets used for connecting steel beams, vary somewhat with different shops and with different structural engineers, so that there cannot be said to be a universal standard. The variations in the different STANDARDS, however, are not very great, and as the connections adopted by the Carnegie Steel Company are perhaps the most used, the author has selected them for illustration in Table XVII. The CONNECTIONS have been proportioned with a view to covering most cases occurring in ordinary practice, with the usual relations of depth of beam to length of span. In extreme instances, however, where beams of short relative span-lengths are loaded to their full capacity, or when beams frame opposite each other into another beam with web-thickness less than 9/16 in, it may be found necessary to make provision for additional strength in the connections. The LIMITING SPAN-LENGTHS, also, at and above which the standard connection-angles may be used with perfect safety, are also given in Table XVIII.

* For details of the framing of floor-beams and girders, see Chapters XXI and XXII and also Professor Nolan's revised Chapters II and VII of Kidder's Building-Construction and Superintendence, Part II, Carpenters' Work.

Allowable Unit Stress in Pounds per Square Inch

Single shear	Rivets..........shop	12 000	Bearing	Rivets, enclosed..shop	30 000
	Rivets and turned bolts...........field	10 000		Rivets, one side..shop	24 000
	Rough bolts......field	8 000		Rivets and turned bolts..........field	20 000
				Rough bolts......field	16 000

t = Web-thickness, in bearing, to develop maximum allowable reactions, when beams frame opposite

Connections are figured for bearing and shear (no moment considered)

The above values agree with tests made on beams under ordinary conditions of use

Where the web is enclosed between connection-angles (enclosed bearing), values are greater because of the increased efficiency due to friction and grip

Special connections must be used when any of the limiting conditions given above are exceeded, as when an end-reaction from a loaded beam is greater than the value of the connection of the shorter span with the beam fully loaded; or a less thickness of web when maximum allowable reactions are used

* From Pocket Companion, 1915 Edition, Carnegie Steel Company, Pittsburgh, Pa.

CHAPTER XVI

STRENGTH OF CAST-IRON LINTELS AND WOODEN BEAMS

By
F. H. KINDL
CORRESPONDING MEMBER AMERICAN INSTITUTE OF ARCHITECTS

1. Cast-Iron Lintels

Form of Cross-Section. Owing to the fact that the resistance of cast iron to tension is only about one-fifth of its resistance to compression, the shapes of beams most economical for wrought iron or steel would be wasteful for cast iron. The extreme brittleness of cast iron, and the danger of flaws in castings, render it an undesirable material for resisting transverse stress. About the only form in which cast-iron beams are now used in building-construction in this country is in the shape of LINTELS for supporting brick or stone walls, in places where a flat soffit is desired, and the walls are not to be plastered. CAST-IRON LINTELS are also occasionally used over store-fronts, the face of the lintel being paneled and molded for architectural effect.

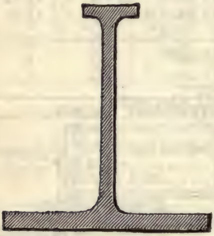

Fig. 1. Cross-section of Cast-iron Lintel of Ideal Form

Experiments on Cast-Iron Beams. Before wrought-iron **I** beams were manufactured, CAST-IRON BEAMS were frequently used as the only available ones, other than those of wood or stone. Early in the nineteenth century Eaton Hodgkinson, an English engineer, made a series of experiments with cast-iron beams, from which he found that the form of cross-section of a beam of that material which will resist the greatest transverse stress is that shown in Fig. 1, in which there is six times more metal in the bottom than in the top flange. The relative thicknesses of the three parts, the web, the top flange and the bottom flange, may be, with advantage, as 5, 6 and 8, respectively.

Strength of Cast-Iron Beams. If made with these proportions, the width of the top flange will be equal to one-third that of the bottom flange. As the result of his experiments, Hodgkinson gave the following rule for the breaking-weight at the middle for a cast-iron beam of this form:

$$\text{Breaking-load in tons} = \frac{\begin{pmatrix}\text{area of bottom flange}\\ \text{in square inches}\end{pmatrix} \times \begin{pmatrix}\text{depth}\\ \text{in inches}\end{pmatrix} \times 2.426}{\text{clear span in feet}} \qquad (1)$$

This rule, although largely empirical, agreed very well with the few experiments that were made. Structural engineers, however, use the general formulas for the strength of beams, as given in Chapter XV, except that the SECTION-MODULUS is found by dividing the MOMENT OF INERTIA by the distance of the neutral axis from the bottom of the beam, and the SAFE TENSILE STRENGTH is

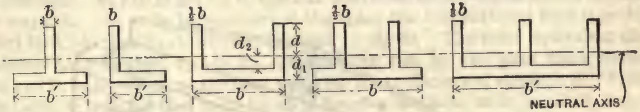
used in the FLEXURE-FORMULA. Thus the general formula for a beam supported at both ends and with the load uniformly distributed, as given in Chapter XV, page 560, is:

Safe load in pounds $= \frac{2}{3} \frac{I/c}{l} \times S_t$. As S_t, the safe tensile strength for cast iron should be taken at 3 000 lb, this formula becomes

$$\text{Safe load in pounds} = \frac{2\,000\, I/c}{l} \tag{2}$$

and, for either section given below,

$$I/c = \frac{\text{Moment of inertia}}{d_1}$$



The MOMENT OF INERTIA is computed by the formula (see page 335)

$$I = \frac{bd^3 + b'd_1^3 - (b' - b)d_2^3}{3} \tag{3}$$

in which b denotes the combined thickness of the webs, and the distances d, d_1, and d_2 are measured from the NEUTRAL AXIS, which must pass through the CENTER OF GRAVITY of the section. The center of gravity may be found by the method explained in Chapter VI. This formula may be used for any of the above sections when the depth does not exceed the width, and the thickness of each web is at least equal to the thickness of the flange. In lintels with a single web it is well to make the thickness of the web ¼ or ⅛ in greater than the thickness of the flange. For a beam with a cross-section like that shown in Fig. 1, Formula (2) agrees very closely with Formula (1), when a factor of safety of six is used.

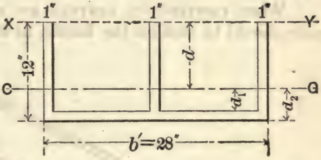


Fig. 2. Cross-section of Cast-iron Lintel with Three Webs

Example. The following example illustrates the application of Formula (2): It is required to compute the safe load for a cast-iron lintel having the section shown in Fig. 2 and a clear span of 10 ft. The load is uniformly distributed, and the thickness of the metal 1 in.

Solution. The first step is the finding of distance d, that the center of gravity, through which the neutral axis of the cross-section passes, is below the top-surface of the beam. This is found by taking the moments of the areas of the cross-sections of webs and flange about the line XY, and dividing their sum by the area of the entire section. (See page 294.) Each web-section is 11 in deep and 1 in thick; hence the area of each is 11 sq in. The MOMENTS OF THE THREE WEBS about XY will then be $3 \times 11 \times 5\frac{1}{2} = 181.5$

The MOMENT OF THE FLANGE about $XY = 28 \times 11\frac{1}{2} = \underline{322}$

503.5

The area of the entire cross-section = 61 sq in

$503.5 \div 61 = 8.25 = d$ in

Then	$d = 8.25$ in	$d^3 = 561.5$	$b = 3$ in
	$d_1 = 3.75$ in	$d_1^3 = 52.7$	$b' = 28$ in
	$d_2 = 2.75$ in	$d_2^3 = 20.8$	

The MOMENT OF INERTIA is next found by Formula (3):

$$I = \frac{3 \times 561.5 + 28 \times 52.7 - 25 \times 20.8}{3} = 880$$

$I/c = 880/3.75$. From Formula (2) the safe load = $(2\,000 \times 234.6)/10 = 46\,920$ lb, or 23.4 tons.

Ends and Brackets of Cast-Iron Lintels. When a lintel, the cross-section of which has the shape of an inverted T (⊥), is used over a single opening, the

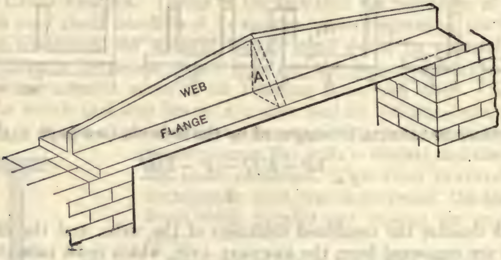

Fig. 3. Cast-iron Lintel with Tapering Web

web may be tapered towards the ends, as in Fig. 3, without affecting the strength. If the flange is more than 8 in wide, brackets should be cast in the middle, as at *A*, Fig. 3.

When CONTINUOUS LINTELS are used over store-fronts or similar places, ends should be cast on the lintels, as in Fig. 4, and the ends of abutting lintels

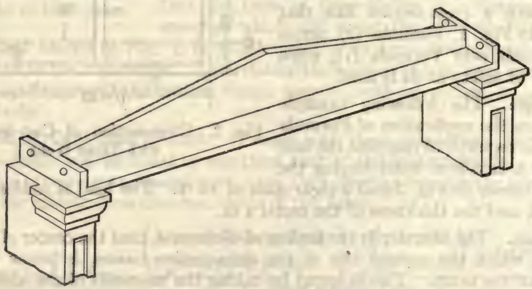

Fig. 4. Cast-iron Lintel with Ends for Bolting

bolted together. All lintels with two or three webs should have solid ends connecting the webs.

Tables of Strength of Cast-Iron Lintels. The tables on the following pages have been computed in accordance with Formula (2). The weight of the

lintel itself should be deducted from the safe load. In using these tables it should be remembered that the values are for loads UNIFORMLY DISTRIBUTED. If the load is CONCENTRATED AT THE MIDDLE, it should be multiplied by 2. If at some other point than the middle, the load should be multiplied by the value given on pages 566 and 632, which most nearly corresponds with the position of the load. For other spans than those given, the distributed load should be multiplied by the span, and the lintel used which has a COEFFICIENT OF STRENGTH C (Table I) just above the product thus obtained. (For explanation of coefficient of strength, see Chapter XV, page 556.)

Example. It is required to support a 12-in brick wall, 10 ft high, over an opening 5 ft 6 in wide, with a cast-iron lintel. At a distance of 22 in from one support, a girder, which may bring a load of 9 600 lb on the lintel, enters the wall. What should be the dimensions of the lintel?

Solution. At 110 lb per cu ft, the wall above the lintel weighs $10 \times 5\frac{1}{2} \times 110 = 6\,050$ lb. As 22 in is one-third of the span, the concentrated load is multiplied by 1.78 (page 632), making the load 17 088 lb. The total equivalent distributed load is then 23 138 lb. Multiplying this by the span there results 127 259 lb, or 63.6 tons, as the least value for the coefficient of strength C. From the table, it is found that a 12 by 10-in lintel, 1 in thick, with one web, has a coefficient of strength of 72.2; and that a 12 by 8 by 1¼-in lintel with two webs, has a coefficient of strength of 69.9. A lintel with two webs is best for a 12-in wall, and interpolating between the values of C for the 1-in and 2-in thicknesses of the 12 by 8-in lintel, 65.4 is found to be the value of C for a thickness of 1⅛ in. This exceeds the required value by enough to more than compensate for the weight of the lintel itself; hence a 12 by 8 by 1⅛-in lintel with two webs is used.

Flaws in Castings. Owing to the liability of flaws in the castings, cast-iron beams should always be carefully inspected before being accepted.

Table I. Safe Distributed Loads in Tons for Cast-Iron Lintels

LINTELS OF  SHAPES

Loads include weights of lintels. Maximum tensile stress 3 000 lb per sq in. See remarks, pages 622 and 623.

2. Sections, Stresses, Buckling and Deflection of Wooden Beams

Sections and Fiber-Stresses. The cross-sections of wooden beams are almost invariably SQUARE OR RECTANGULAR, and those shapes only are considered in the following rules and formulas. Beams should have such a cross-section, that the maximum fiber-stress due to transverse bending, the maximum horizontal shear and the compression across the grain at the end-bearings, do not exceed the AVERAGE ALLOWABLE UNIT STRESSES as set forth in Table XVI, page 647.

Buckling. Beams should be braced laterally to prevent BUCKLING when the ratio of length to breadth exceeds twenty, or designed with a reduced fiber-stress from that allowable, where this ratio is exceeded. The PERCENTAGE OF REDUCTION should be as follows:

Ratio of length to width......	20 to 30	30 to 40	40 to 50	50 to 60
Percentage of reduction......	25	34	42	50

Deflection. It is also important that beams carry the loads without DEFLECTING beyond a limit fixed by the use to which the structure is applied; this limit is generally taken at 1/30 of an inch per foot of span for plastered ceilings.

3. Constants and Coefficients for Beams

Value of the Constant, A. The letter A in the following formulas (4) to (16), denotes the SAFE LOAD for a UNIT BEAM, 1 in square in section and 1 ft in span, loaded at the middle of the span. This is also one-eighteenth of the ALLOWABLE FIBER-STRESS in pounds per square inch. (See Table I, on page 557.) The following are the values of A, obtained by dividing by eighteen the RECOMMENDED UNIT STRESSES for TRANSVERSE BENDING, and those given in the building laws of New York, Chicago, Baltimore and Boston.

Table II.* Coefficients for Iron, Steel and Wooden Beams. Values for A in Formulas

Materials	New York	Chicago	Baltimore	Boston	Recommended †
Cast iron..............	167	167	167	167	167
Wrought iron..........	667	667	667	667	667
Steel..................	889	889	889	889	889
Yellow pine...........	90	72	100	83	67
White pine............	67	44	56	56	39
Spruce................	67	44	75	56	39
Hemlock...............	44	33	....	....	33
Chestnut..............	....	....	....	....	44
Oak...................	67	67	83	56	67
Douglas fir...........	67	72	....	....	56

* For safe allowable working unit stresses for other woods, see Table XVI, page 647. From these values, A may be determined by dividing them by eighteen. See Table XVII, page 648, for other stresses for woods, taken from various building laws. See Tables XVIII and XIX, pages 650 and 651, for the ultimate strength of woods.

† The values of A for wooden beams may be increased from 30 to 40% for temporary structures, and for commercially dry and protected timber, not subject to impact, or for ideal conditions.

Table III. Coefficients Recommended for Stone ‡ and Concrete Beams. Values of A

Materials	Values of A	Materials	Values of A
Granite..................	10	Bluestone................	17
Limestone................	8	Slate....................	22
Marble...................	7	Concrete 1 : 2 : 4..........	1.7
Sandstone................	6	Concrete 1 : 2 : 5..........	1.1

‡ Values of A for STONE BEAMS were taken from former Building Laws of New York and from the requirements of the Board of Fire Underwriters.

4. Flexural Strength of Wooden Beams

Section-Modulus. For beams with a rectangular cross-section, the formulas for strength can be simplified by substituting for the SECTION-MODULUS its value $\frac{1}{6}bd^2$, where b is the breadth and d the depth of the section.

Substituting this value in the general formulas for beams with rectangular cross-sections and of any material, the following formulas result:

Beams Fixed at One End and Loaded at the Other (Fig. 5).

$$\text{Safe load, in pounds} = \frac{\text{breadth} \times \text{square of depth} \times A^*}{4 \times \text{length in feet}} \tag{4}$$

or

$$\text{Breadth, in inches} = \frac{4 \times \text{load} \times \text{length in feet}}{\text{square of depth} \times A^*} \tag{5}$$

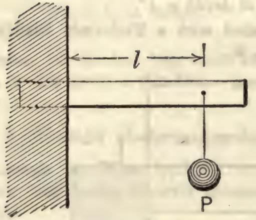

Fig. 5. Cantilever Beam. Load near Free End

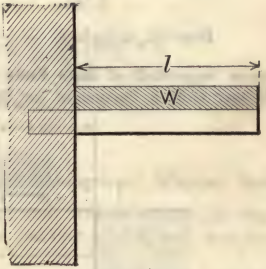

Fig. 6. Cantilever Beam. Distributed Load over Entire Span

Beams Fixed at One End and Loaded with a Uniformly Distributed Load (Fig. 6).

$$\text{Safe load, in pounds} = \frac{\text{breadth} \times \text{square of depth} \times A^*}{2 \times \text{length in feet}} \tag{6}$$

or

$$\text{Breadth, in inches} = \frac{2 \times \text{load} \times \text{length in feet}}{\text{square of depth} \times A^*} \tag{7}$$

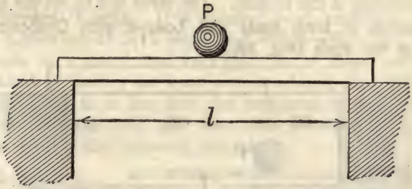

Fig. 7. Simple Beam. Load at Middle of Span

Beams Supported at Both Ends and Loaded at the Middle (Fig. 7).

$$\text{Safe load, in pounds} = \frac{\text{breadth} \times \text{square of depth} \times A^*}{\text{span in feet}} \tag{8}$$

or

$$\text{Breadth, in inches} = \frac{\text{span in feet} \times \text{load}}{\text{square of depth} \times A^*} \tag{9}$$

* For values of A, see Tables II and III.

Beams Supported at Both Ends and Loaded with a Uniformly Distributed Load Over Entire Span (Fig. 8).

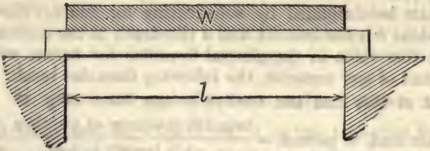

Fig. 8. Simple Beam. Distributed over Entire Span

$$\text{Safe load, in pounds} = \frac{2 \times \text{breadth} \times \text{square of depth} \times A^*}{\text{span in feet}} \qquad (10)$$

or

$$\text{Breadth, in inches} = \frac{\text{span in feet} \times \text{load}}{2 \times \text{square of depth} \times A^*} \qquad (11)$$

Beams Supported at Both Ends and Loaded with a Uniformly Distributed Load Over Only a Portion of the Span (Fig. 9).

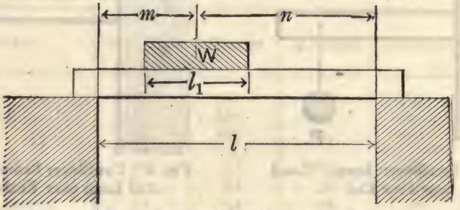

Fig. 9. Simple Beam. Distributed Load over Part of Span

In this case the dimensions of the beam required to carry the load can be accurately determined only by computing the MAXIMUM BENDING MOMENT, as explained in Chapter IX, and substituting the value thus found in Formula (16), following. If, however, the length l_1 is very short in comparison with l, then the load may be considered as CONCENTRATED at the middle of the span and the breadth of the beam may be found by Formula (9). Formula (13) is used if the load is at one side of the middle. The error will be on the safe side.

Beams Supported at Both Ends and Loaded with Concentrated Load, not at the Middle of the Span (Fig. 10).

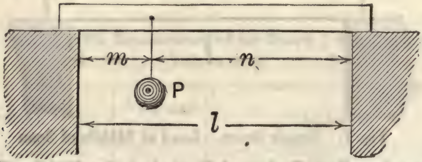

Fig. 10. Simple Beam. Concentrated Load at Any Point

$$\text{Safe load, in pounds} = \frac{\text{breadth} \times \text{square of depth} \times \text{span} \times A^*}{4 \times m \times n} \qquad (12)$$

or

$$\text{Breadth, in inches} = \frac{4 \times \text{load} \times m \times n}{\text{square of depth} \times \text{span} \times A^*} \qquad (13)$$

* For values of A, see Tables II and III.

Beams Supported at Both Ends and Loaded with P Pounds at a Distance m, from each End (Fig. 11).

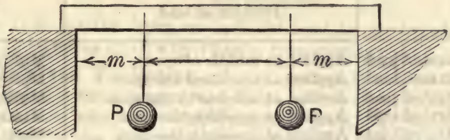

Fig. 11. Simple Beam. Two Equal Concentrated Loads Symmetrically Placed

$$\left.\begin{array}{l}\text{Safe load, } P\text{, in pounds}\\ \text{at each point}\end{array}\right\} = \frac{\text{breadth} \times \text{square of depth} \times A^*}{4 \times m} \qquad (14)$$

or

$$\text{Breadth, in inches} = \frac{4 \times \text{load at one point} \times m}{\text{square of depth} \times A^*} \qquad (15)$$

Note. In the last two cases the lengths denoted by *m* and *n* should be in feet, as the spans are in feet.

5. Application of Formulas for Flexural Strength of Wooden Beams

Example 1. What load, 6 ft out from the wall, will an 8 by 14-in long-leaf yellow pine beam, securely fastened at one end into a brick wall, sustain with safety?

Solution. The safe load in pounds (Formula 4) $= \frac{8 \times 196 \times 67}{4 \times 6} = 4\,377$ lb

Example 2. It is desired to suspend two loads of 10 000 lb each, 4 ft from each end of an oak beam, 20 ft long. What should be the size of the beam?

Solution. Let the depth of the beam be assumed to be 16 in. Then (Formula 15)

$$\text{The breadth} = \frac{4 \times 10\,000 \times 4}{256 \times 67} = 9.3 \text{ in, nearly}$$

The beam, therefore, should be 10 by 16 in in cross-section.

Beam with Several Loads. It is required, next, to determine the size of a beam which is supported at both ends, and which will safely support several concentrated loads, or a distributed load and one or more concentrated loads. The correct method of finding the least size of a beam that will safely support a combination of loads, is to first find the MAXIMUM BENDING MOMENT, as explained in Chapter IX, page 329, and then substitute the value thus found for this BENDING MOMENT in the following formula:

$$\text{Breadth, in inches} = \frac{4 \times \text{maximum bending moment in ft-lb}}{\text{square of depth} \times A} \qquad (16)$$

A shorter and easier method is to find the EQUIVALENT DISTRIBUTED LOAD for each concentrated load, and then find the size of a beam required to support the total equivalent distributed load thus found. The equivalent distributed loads for concentrated loads applied at different proportions of the span from either end, may be obtained by multiplying the concentrated loads by the following FACTORS:

* For values of *A*, see Tables II and III.

Table IV. Factors for Equivalent Distributed Loads

	Position of load	Factor
For a concentrated load	Applied at middle of span	Multiply by 2.
For a concentrated load	Applied at one-third the span	Multiply by 1.78
For a concentrated load	Applied at one-fourth the span	Multiply by 1.5
For a concentrated load	Applied at one-fifth the span	Multiply by 1.28
For a concentrated load	Applied at one-sixth the span	Multiply by $1\frac{1}{9}$
For a concentrated load	Applied at one-seventh the span	Multiply by 0.98
For a concentrated load	Applied at one-eighth the span	Multiply by $\frac{7}{8}$
For a concentrated load	Applied at one-ninth the span	Multiply by 0.79
For a concentrated load	Applied at one-tenth the span	Multiply by 0.72

(See, also, Chapter XV, Safe Loads for Steel Beams, page 566.)

Thus, a concentrated load of 900 lb, applied at one-sixth the span from one support, will result in the same maximum bending moment as a distributed load of $900 \times 1\frac{1}{9}$, or 1 000 lb.

The above method for finding the size of a beam for a combination of several loads gives a larger beam than the correct method, by Formula (16), for the reason that the maximum bending moment will not be equal to the sum of the individual bending moments. Hence, when there are several heavy loads to be supported, it is economical to compute the maximum bending moment by the GRAPHIC METHOD explained in Chapter IX, page 329.

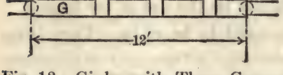

Fig. 12. Girder with Three Concentrated Loads

Example 3. The girder *G*, Fig. 12, supports the rafters of a flat roof, and also three heavy beams, *A*, *B* and *C*, blocked up above the roof and supporting a large tank filled with water. The timber is to be long-leaf yellow pine. The weight of the roof and allowance for snow is 7 500 lb. Each of the beams *A*, *B* and *C*, impose a load on the girder, due to the weight of the tank and its contents, of 3 000 lb. What should be the size of the girder?

Solution. The roof-load may be considered to be uniformly distributed. The load from beam, *A*, is applied at one-third the span from one end; the load from *B*, five-twelfths the span from the other end; and the load from *C*, one-sixth the span. The fraction five-twelfths is the mean of one-half and one-third; hence the load from *B* should be multiplied by 1.89. Multiplying the concentrated loads by their proper factors, the equivalent distributed load is found to be as follows:

Roof-load, distributed,	=	7 500
Load from *A*, $3\,000 \times 1.78$	=	5 340
Load from *B*, $3\,000 \times 1.89$	=	5 670
Load from *C*, $3\,000 \times 1\frac{1}{9}$	=	3 333
Equivalent distributed load	=	21 843 lb

Assuming 16 in as the depth of the beam, and using Formula (11),

$$\text{The breadth} = \frac{12 \times 21\,843}{2 \times 256 \times 67} = 7.6 \text{ in}$$

Assuming 14 in for the depth, 10 in is obtained for the breadth; hence, the girder must be 10 by 14 in, or 8 by 16 in in cross-section.

Strut-Beams and Tie-Beams. A STRUT-BEAM is a beam that is subject to both a transverse and a compressive stress. A TIE-BEAM is one that is subject to direct tension in addition to the transverse stress. To find the strength of either, first find the size of a beam required to resist the transverse stress, and then the size of a timber, of the same depth as the beam, to resist the direct tension or compression, and add the two breadths together.

Example 4. A spruce tie-beam, 10 ft long between joints, sustains a ceiling-load of 2 000 lb and a direct tensile stress of 40 000 lb. What should be the dimensions of the beam?

Solution. As a ceiling-load is uniformly distributed, the size of the beam is determined by Formula (11), page 630. Assuming the depth to be 10 in

$$\text{The breadth} = \frac{10 \times 2\,000}{2 \times 100 \times 39}, \quad \text{or} \quad 2\tfrac{1}{2} \text{ in, nearly}$$

The resistance of spruce to tension (see Table XVI, page 647) is 800 lb per sq in. 40 000/800 = 50 sq in, which is equivalent to a 5 by 10-in section. It will require, therefore, a beam 7½ by 10 in in cross-section to resist both the transverse stress and the direct tension. If the tie-beam is cut in any way so as to reduce the section, except over a support, the dimensions must be increased accordingly.

Example 5. A strut-beam of white pine, 10 ft long, supports a distributed roof-load of 6 000 lb, and is also subject to a direct compression of 64 000 lb. What should be the size of the beam?

Solution. Assuming 14 in for the depth, the breadth for the transverse load is found by Formula (11), page 630

$$\text{The breadth} = \frac{10 \times 6\,000}{2 \times 196 \times 39} = 3.9 \text{ in, nearly}$$

Using Formula (4), page 450, from which is computed Table IV, page 452, giving the safe loads for white-pine posts, it is found that a 7½ by 14-in post, 10 ft long will safely carry the compressive stress, 64 000 lb. Hence it will require a 7½ by 14-in beam to resist the compressive stress, and a 4 by 14-in beam to resist the transverse load. The beam, therefore, should be 12 by 14 in in cross-section to resist them both.

6. Relative Strengths of Beams

Relative Strengths of Rectangular Beams. From an inspection of the foregoing formulas it is found that the RELATIVE STRENGTHS of beams of rectangular cross-sections, for the different cases is as shown in Table V.

Strengths of Beams of Any Constant Cross-Section. The STRENGTH-RATIOS given in Table V are true for beams of any constant cross-section of whatever form.

Beam on Edge. When a beam of square cross-section is supported on its edge, that is, when one of its diagonals is vertical, it will bear about seven-tenths as great a breaking-load as it will when it is supported on one side.

Table V. Relative Strengths of Rectangular Beams

Kind of load	Position of load	Strength ratios
Beam supported at both ends		
Uniformly distributed	Over entire span	1
Concentrated	At middle of span	1/2
Concentrated	At one-third the span	9/16
Concentrated	At one-fourth the span	2/3
Concentrated	At one-fifth the span	25/32
Concentrated	At one-sixth the span	9/10
Concentrated	At one-seventh the span	49/48
Concentrated	At one-eighth the span	8/7
Concentrated	At one-ninth the span	81/64
Concentrated	At one-tenth the span	25/18
Beam fixed at one end, or cantilever beams		
Uniformly distributed	Over entire span	1/4
Concentrated	At the free end	1/8
Beam supported at one end and fixed at the other end		
Uniformly distributed	Over entire span	1
Concentrated	Near the middle of span	1 3/20
Beam fixed at both ends		
Uniformly distributed	Over entire span	1 1/2
Concentrated	At middle of span	1

The Strongest Beam Cut From a Cylindrical Log is one in which the breadth is to the depth as 5 is to 7, very nearly, and the dimensions of such a beam can be found graphically, as shown in Fig. 13. Any diagonal, as *ab*, is drawn and divided into three equal parts by the points *c* and *d*; from these points lines perpendicular to *ab* are drawn, and the points *e* and *f* connected with *a* and *b*, as shown.

Fig. 13. Strongest Beam of Rectangular Section Cut from Log

Cylindrical Beams. A CYLINDRICAL BEAM is only ten-seventeenths as strong as a beam with a square cross-section, the side of the square being equal to the diameter of the circular section of the cylindrical beam. Hence, to find the safe load for a cylindrical beam, first find the proper load for the corresponding square-section beam, and divide this load by 1.7.

The Bearing of the Ends of a Beam on a wall beyond a certain distance does not strengthen the beam. In general, a beam should have a bearing of 4 in, or if it is very long, 6 in.

The Weight of the Beam Itself. The formulas given for the strength of beams do not take into account the WEIGHT OF THE BEAMS THEMSELVES, and hence the safe loads of the formulas include both the external loads and the weights of the material in the beams. In small wooden beams, the weight of

each beam is generally so small, compared with the external load, that it need not be taken into account. But for larger wooden beams, and for metal and stone beams, the weight of the beam should be subtracted from the safe load if the load is distributed; and if the load is applied at the middle, one-half the weight of the beam should be subtracted.

The Weight of Timber. The weight per cubic foot for different kinds of timber may be found in the table in Part III, pages 1415 to 1422, giving the Weights of Various Substances.

7. Tables for Strength and Stiffness of Wooden Beams

Tables VII to XV for the Strength and Stiffness of Wooden Beams are given on pages 638 to 646, for BEAMS ONE INCH IN BREADTH. To find the strength for any other breadth, multiply the proper tabular value by the breadth of the beam in inches. To obtain the required breadth for any load, divide the given load in pounds by the proper tabular value. In heading the tables, prominence has been given to the values used for S, and the corresponding values of A, so that those who prefer to use for any wood a value different from that recommended, need only to look up the table based on the value they desire to employ. For certain cases and in some cities, the building laws specify 1 300, 1 500 and 1 800 pounds as values of S to be used for long-leaf yellow pine; hence Tables XIII, XIV and XV, based on these values, are added.

Since timber is very weak in SHEARING in comparison with its strength in TENSION and COMPRESSION, the safe load a beam of short span can carry is governed, not by its resistance to CROSS-BREAKING, but by its RESISTANCE to SHEARING along the NEUTRAL SURFACE. Wooden beams and joists, therefore, should be dimensioned to safely withstand this SHEARING ACTION. The ratio of the SHEARING to the FLEXURAL STRENGTH is not exactly the same for different kinds of wood, but for practical use and in the tables it has been assumed to be one-twelfth of the WORKING UNIT FIBER-STRESS. As it can be shown * that the ratio of the span to the depth of a rectangular beam, uniformly loaded, is directly proportional to its CROSS-BREAKING STRESS and SHEARING WORKING STRESS, the tabular loads are figured for the PERMISSIBLE UNIT FIBER-STRESS, where the length of the span is twelve or more times the depth of the beam; while for shorter lengths, the tabular loads are governed by the SHEAR. To determine the safe load on beams for a deflection not exceeding 1/360 of the span, tabular values have been placed directly underneath the safe loads for strength. These values are based on the MODULUS OF ELASTICITY, E, given in the tables.

The FORMULA FOR FLEXURE used in determining the safe uniformly distributed loads in the tables is (see Formulas (1), page 333 and (2)′, page 557)

$$M = \frac{SI}{c} = \frac{Sbd^2}{6} = \frac{Wl}{8}$$

Hence $$W = \frac{4}{3}\frac{bd^2S}{l},\text{ in which } l \text{ is the span in inches}$$

The FORMULA FOR SHEAR is

$$W = \frac{4\,bdS_s}{3}$$

* Materials of Construction, J. B. Johnson, page 55.

The FORMULA FOR DEFLECTION is (see, also, Formulas (1) to (17) and Table I, Chapter XVIII)

$W = \dfrac{Ed^3}{8\,100\,l^2}$ in which l is the span in feet;

M = maximum bending moment in inch-pounds;

I = moment of inertia of the cross-section of the beam in biquadratic inches;

$c = d/2$ = one-half the depth of the beam in inches;

SI/c = resisting moment of the cross-section in inch-pounds;

W = total safe load in pounds, uniformly distributed;

b = breadth of the beam in inches;

d = depth of the beam in inches;

l = span, in feet or inches, as noted for the different formulas;

S = unit flexural fiber-stress in pounds per square inch;

$S_s = S/12$ = horizontal unit shearing-stress, in pounds per square inch, along the neutral surface;

E = modulus of elasticity in pounds per square inch.

Example 6. What is the safe, uniformly distributed load, corresponding to a fiber-stress of 1 200 lb per sq in, for an 8 by 14-in long-leaf yellow-pine beam, supported at both ends, and having a 24-ft clear span?

Solution. From Table XII, the load for a 1-in thickness is 1 090 lb. Hence, 1 090 × 8 = 8 720 lb, the total load for the beam. If the deflection of this beam should not be more than 1/360 of the span, the safe load for a 1-in thickness should not exceed 882 lb. Hence, 882 × 8 = 7 056 lb, is the maximum load to be used in this case.

Example 7. What should be the size of a Norway-pine beam required to carry a distributed load of 6 400 lb over a clear span of 18 ft?

Solution. From Table X, it is found that a beam 12 in deep and 1 in thick and with an 18-ft span, will support 711 lb. Dividing the load, 6 400 lb, by 711, the result is 9 for the breadth of the beam in inches. Hence the beam should be 9 by 12 in, to carry a distributed load of 6 400 lb over a span of 18 ft. As the deflection-load of 593 lb can be increased 20% for Norway pine, the beam is safe for deflection; if, however, cypress is used, 593 must be taken in place of 711, to determine the breadth of the beam. This would result in a beam 11 by 12 in.

Different Positions of Loads. To find the safe load, concentrated at the middle of the span of a given beam, find the safe distributed load, as in Example 6, and divide this load by 2. To find the safe load concentrated at some point other than the middle of the span, find the safe distributed load for the given span, and divide this load by the proper factor taken from Table IV, page 632. To find the size of a beam to support a given concentrated load, multiply the given load by the factor corresponding to the position of the load, as given in Table IV, and then proceed as in Example 7.

Use of Formulas. If in doubt as to the application of the tables, in special cases, use one of the formulas, from (4) to (16), applying to the case. The formulas and tables should always give the same result.

Nominal and Actual Sizes of Beams. The tables may be used for beams the dimensions of which are less than the NOMINAL DIMENSIONS. Dressed beams, and, in many localities, floor-joists carried in stock, are more or less scant of the nominal dimensions, and for such beams and joists a reduction in the safe load must be made to correspond with the reduction in size. The

DRESSED SIZES are generally ¼ in scant, up to 4 in in breadth, above which they are ½ in scant; while in depth they are all generally ½ in less than the nominal size. The safe loads may be obtained by multiplying the safe loads for the corresponding nominal sizes, as given in Tables VII to XV, by the factors given in the following table.

Table VI. Conversion Factors for Actual Sizes of Wooden Beams

Cross-sections of beams in inches	Factors	Cross-sections of beams in inches	Factors
1¾ × 5½	1.47	1¾ × 11½	1.61
2¾ × 5½	2.31	2¾ × 11½	2.53
1¾ × 6½	1.51	1¾ × 13½	1.63
2¾ × 6½	2.51	2¾ × 13½	2.56
1¾ × 7½	1.54	1¾ × 15½	1.65
2¾ × 7½	2.42	2¾ × 15½	2.58
1¾ × 9½	1.58	1¾ × 17½	1.65
2¾ × 9½	2.48	2¾ × 17½	2.60

Example 8. What is the safe load for a 2¾ by 13½-in spruce beam, with an 18-ft span?

Solution. From Table VIII, the safe load for a 1 by 14-in beam is 847 lb. Multiplying this by 2.56, we have 2 178 lb as the safe distributed load for a beam 2¾ by 13½ in in cross-section. For a full 3 by 14-in cross-section, the safe load would be 2 541 lb.

Stone Beams. The above formulas may be used for rectangular stone beams when the proper coefficients, recommended in Table III, page 628, are inserted. Sandstone beams should never be subjected to any heavy loads and sandstone lintels should be relieved by steel beams or by brick arches over them or back of them.

Concrete Beams are generally reinforced with steel rods, but when used without reinforcement, the coefficient, A, given in Table III, is recommended.

Use of Tables VII to XV. The safe loads given in Tables VII to XV are correct for the fiber-stresses indicated; but for greater convenience in using the tables, each figure in the units-place of each value may be made a cipher, and each figure in the tens-place may be increased by one when the unit-figure is six or greater. Thus, 505 would be 500, 506 would be 510, etc.

Important Notes on Stresses and Loads for Wooden Beams. In compiling and using the tables of safe loads for wooden beams, the following important considerations must be kept in mind:

(1) Unseasoned timber is very much weaker than commercially dry timber, that is, timber containing from 10 to 15% of moisture.

(2) Timber containing large or loose knots is much weakened.

(5) When impact has to be considered, the stresses should be reduced.

(4) For continuous, heavy loading, relatively low stresses should be used.

(5) Commercial dimensions are smaller than nominal dimensions.

(6) Timbers deteriorate and the factors of safety for strength grow smaller with time.

(7) The modulus of elasticity, E, for unseasoned timber should be reduced 50% from its value for thoroughly seasoned timber.

(8) It is better engineering practice to compute tables of safe loads based on conservative stresses for average or poor conditions, increasing the values given when conditions are ideal, than to recommend values for ideal conditions which usually do not eixst. (See, also, notes on pages 628 and 647, regarding increase in the table-values.)

Loads above the heavy, black zigzag lines are calculated for resistance to shear.

8. Working Unit Stresses for Average, Unseasoned Woods

Safe Working Unit Stresses for unseasoned woods are given in Table XVI. They are compiled and adapted largely from recommended UNIT STRESSES adopted by the Association of Railway Superintendents of Bridges and Buildings and by the American Railway Engineering Association. (See, also, page 449.)

Table XVI. Safe Working * Unit Stresses for Unseasoned Woods, in Pounds per Square Inch

Kind of wood	Tension		Compression			Bending †		Shearing	
	With the grain	Across the grain	With the grain: End-bearing	With the grain: Columns‡ under 15 diams	Across the grain	Extreme fiber-stress §	Modulus of elasticity, ‖ $E/1000$	With the grain	Across the grain
Factor of safety	Ten	Ten	Five	Five	Four	Six	One	Four	Four
White oak	1 200	200	1 400	1 000	500	1 200	1 500	200	1 000

Chestnut	850	.....	....	800	250	800	1 000	150	500
California red wood	700	.....	900	800	150	750	700	75	.....

* The stresses given may be increased 30% for protected, commercially dry timber, not subject to impact, as in most buildings.

† See also, Table I, page 557, Table XVII, page 648 and Table I, page 1138.

‡ The larger end-bearing stresses are frequently used for short columns and for column-formulas. (See tables, pages 449, 1138.) Lower factors of safety give higher stresses.

§ Some of these values are considered too low, relatively, by some building codes.

‖ These values of E are for seasoned timber, and good conditions.

¶ The New York Building Code (1916) stresses are based upon relative values 20 to 30% higher.

9. Working Unit Stresses for Woods. Taken from Building Laws.

The Allowable Working Unit Stresses for different woods, taken from the building laws of four cities, are given in Table XVII. The UNIT STRESSES are for TENSION, COMPRESSION, BENDING and SHEAR.

Table XVII. Working Unit Stresses for Woods, in Pounds per Square Inch

* Stresses named by N. Y. are given in the 1916 Building Code of the Borough of Manhattan. Exceptions: Dist. of Columbia omits hemlock, omits chestnut in shear across grain and puts spruce and Virginia pine under one caption; Cincinnati makes caption of white pine and spruce, with N. Y. white-pine values, and gives 270 for hemlock, for shear across grain. † Chicago, "Douglas fir and long-leaf yellow pine." ‡ Chicago, no values for spruce; spruce-values apply to Norway pine. ‖ Chicago, values given for short-leaf yellow pine, SLYP. § Baltimore, LLYP is long-leaf yellow pine; NC or VP, N. Carolina or Virginia pine. ¶ Boston, yellow pine is "yellow pine (long-leaf)."

10. Ultimate Unit Stresses for Woods

The Average Ultimate Unit Stresses for the CONIFEROUS OR SOFTWOODS and for the BROAD-LEAVED OR HARDWOODS, together with the AVERAGE WEIGHTS of the woods per cubic foot are given in Tables XVIII and XIX. The values given are compiled from many tests on numerous species of timber. In regard to the range of values for the same kind of wood, it may be stated that the higher values are for specimens which contained a percentage of water varying from 15 to 20%; and that tests on laboratory specimens showed greater strength than the actual pieces used in construction. The WEIGHTS PER CUBIC FOOT are averages of the weights of many specimens tested and agree generally with average values given in other tables of weights of materials.

Table XVIII.* Average Ultimate Unit Stresses for the Coniferous or Softwoods, in Pounds per Square Inch

Kind of wood	Weight in lb per cu ft, dry	Tension	Compression		Bending (modulus of rupture)	Shear	
			With the grain	Across the grain		With the grain	Across the grain
Cedar (white)	19.72 to 20.70	8 000 to 11 400	4 000 to 6 000	700	5 000	400	1 300 to 1 519
Cedar (red)	23.66	8 000	4 000 to 7 000	700	5 000	......	1 500
Cypress	29.80	4 000 to 6 000	4 000 to 8 000	700 to 800	5 000 to 11 700	500	......
Hemlock	26.42 to 32.29	6 000 to 8 700	4 000 to 7 420	600 to 700	3 500	350	2 500 to 2 750
Pine (white)	25.55	3 000 to 12 000	3 000 to 6 650	700 to 1 000	4 000 to 10 000	225 to 423	2 480
Pine (red), (Norway pine)	30.25	5 000 to 13 000	6 000 to 8 000	800 to 1 000	5 000 to 12 300	500	......
Pine (yellow), (long-leaf)	43.62	6 000 to 13 000	5 000 to 9 500	1 000 to 1 400	7 000 to 14 200	300 to 700	4 340 to 5 000
Pine (yellow), (short-leaf)	38.40	5 000 to 10 000	4 000 to 9 000	900 to 1 000	6 000 to 12 400	400 to 700	4 000 to 5 000
Douglas fir (Oregon pine)	32.14	9 000 to 14 000	4 880 to 9 800	800 to 1 200	6 500 to 12 100	500 to 600	....
Redwood (California)	26.23	7 000 to 10 853	3 000 to 4 000	800	4 500	400	......
Spruce (black)	28.57	5 000 to 19 500	4 000 to 7 850	700	4 000 to 12 000	250 to 400	3 255
Spruce (white)	25.25	5 000 to 19 500	4 000 to 7 850	700	4 000 to 12 000	250 to 400	3 255

* The higher values of tensile and compressive strengths are for "dry" or "seasoned" timber containing from 10 to 15% of water. For safe fiber-stresses for flexure, see Table I, page 557.

Table XIX.* Average Ultimate Unit Stresses for the Broad-Leaved or Hardwoods, in Pounds per Square Inch

Kinds of wood	Weight in lb per cu ft, dry	Tension	Compression		Bending (modulus of rupture)	Shear	
			With the grain	Across the grain		With the grain	Across the grain

* The higher values of the tensile and compressive strengths are for "dry" or "seasoned" timber containing from 10 to 15% of water. For safe fiber-stresses for flexure, see Table I, page 557.

CHAPTER XVII

STRENGTH OF BUILT-UP, FLITCHED AND TRUSSED WOODEN GIRDERS

By

F. H. KINDL

CORRESPONDING MEMBER AMERICAN INSTITUTE OF ARCHITECTS

1. Built-Up Wooden Girders

Built-Up Wooden Beams. Wooden beams or girders built up of planks, spiked or bolted together side by side, will generally be somewhat stronger than solid girders of the same dimensions, because the planks will be better seasoned and freer from check-cracks and other defects. For beams or girders 10 in or less in depth, spikes will usually be sufficient to bind the planks together; but for deeper beams, bolts should be used in addition to the spikes, to prevent the planks from separating and the outer planks from warping or curling away from the others.

Bolts. Two bolts should be placed at each end of the beam and every four feet of its length.

Lengths of Planks. When a beam is built up in this way each plank should extend the full length of the beam. In a CONTINUOUS BEAM, the planks should break joints over the supports. The planks of BUILT-UP BEAMS should always be set on edge, never flatwise.

Compound Wooden Beams. It is sometimes necessary to use a wooden beam for a longer span or greater load than is safe for the deepest SINGLE BEAM that can be obtained, or for a beam built up of planks. In such cases COMPOUND WOODEN BEAMS may be used.

Definition. By a COMPOUND WOODEN BEAM OR GIRDER is meant a beam built up by placing two or more single beams over another one, with the view of having them act as a SINGLE BEAM having the depth of the combined beams.

Fig. 1. Two Simple Wooden Beams, One Over the Other, Loaded in Middle

Strength of Compound Beams. If two 10 by 10-in beams were placed one on top of the other, and the upper one loaded at the middle, the beams would act as two separate beams (Fig. 1) and their combined strength would be no greater than if the two beams were placed side by side. If, however, the two beams can be joined so that the fibers of the lower beam will be extended as much as would be the case in a single beam of the same depth, or, in other words so that the two beams will not slip on each other, the COMPOUND BEAM will have four times the strength of the SINGLE BEAM.

Tests of Compound Beams. Various attempts have been made to join beams thus placed so as to prevent the two parts slipping on each other, and

during the years 1896–7, Edgar Kidwell, of the Michigan College of Mines, made an extended series of tests of the efficiency of COMPOUND BEAMS of different patterns. From these tests much valuable data was obtained. A full description of the tests, accompanied by the conclusions of the author, and the rules and data for proportioning the bolts and keys, of KEYED BEAMS, is published in the Trans. Am. Soc. M. E., vol. 27.

Simple Form of Compound Beam. A form of COMPOUND BEAM, sometimes used in American building-construction, is shown in Fig. 2, diagonal boards in opposite directions being nailed to each side of the two timbers to prevent their slipping on each other. T. M. Clark, in his Building Superintendence, advocates this as one of the best forms of compound beams, and

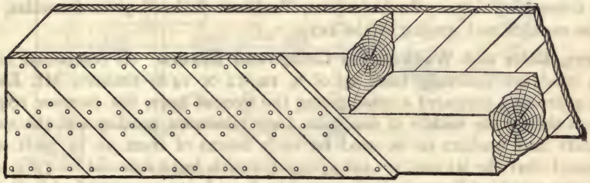

Fig. 2. Simple Form of Compound Wooden Beam

places its EFFICIENCY at about 95% of that of a solid beam of the same depth. Professor Kidwell made nine tests of this type of beam. In six of the beams the ratio of span to depth was as 12 to 1, and in three of the beams, as 24 to 1. The shorter beams gave an average EFFICIENCY, without much variation, of 71.4%, and the longer beams an EFFICIENCY of 80.7%.

It was found that the beams failed by the splitting of the diagonal pieces or the drawing of the nails; "in every case, long before the beam broke, the struts split open or the nails were partly drawn out or bent over in the wood, thereby permitting the component beams to slide on each other." When built with diagonal boards, 1¼ in thick, nailed with tenpenny nails, as in Fig. 2, the WORKING STRENGTH of such a beam may be taken at 65% of the strength of

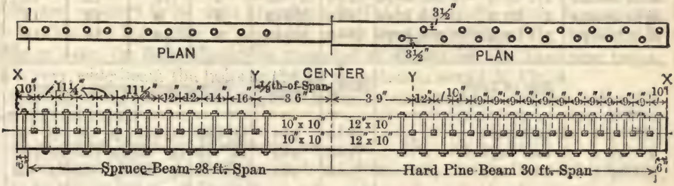

Fig. 3. Compound Keyed and Bolted Wooden Beams

a solid beam of the same depth and of a breadth equal to the breadth of the timbers. The DEFLECTION of the beam, however, will be about double that of a solid beam of the same size, and on that account this type of beam is not to be recommended for supporting floors with plastered ceilings or for carrying plastered partitions.

Keyed Beams. Professor Kidwell tested, also, several types of KEYED BEAMS, and found that a compound beam keyed and bolted together, as shown in Fig. 3, is the most efficient form that it is practical to build.

It was found that with oak keys it was possible to obtain an EFFICIENCY for spruce beams of 95%, while the DEFLECTION varied from 20 to 25% more than would be expected in a solid beam.

Cast-Iron Keys. By using CAST-IRON KEYS the deflection was found to be but little, if any, greater than for a solid beam.

Shape of Keys. The keys must be wedge-shaped, as shown in Fig. 4, so that they can be driven tightly against the end-wood.

Efficiency of Keyed Beams. Professor Kidwell recommends that for ordinary purposes an EFFICIENCY of 75% be allowed when oak keys are used and of 80% when the keys are of cast iron. The width of an oak key should be twice its height. Numerous small keys closely spaced gave better results than fewer large keys. In his report, Professor Kidwell gives formulas, also, for the number and spacing of the keys.

Keys, Bolts and Washers for Compound Beams. As compound beams, when used, are generally built up of 8, 10, 12 or 14-in timbers, Mr. Kidder, some years ago, prepared a table giving the sizes of keys, the number required on each side of the middle of the span, their minimum spacing and the sizes of the bolts and washers to be used for such beams of from 20 to 36-ft spans. He noted that the MAXIMUM SAFE LOADS for such beams should be 75% of the loads computed by Formula (10), page 630, for a beam supported at both ends, and loaded with a uniformly distributed load.

Table I. Keys, Bolts and Washers for Compound, Keyed Wooden Beams

Size of beams	Size of keys	Bolts	Washers	Number of keys each side of center line			
				White pine	Spruce	Douglas fir	Long-leaf yellow pine
16-in beams	1½ by 3 -in oak keys	¾-in	3 -in	7	8	11	12
20-in beams	1½ by 3 -in oak keys	¾-in	3 -in	9	11	13	15
24-in beams	2 by 4 -in oak keys	⅞-in	3½-in	8	9	12	14
28-in beams	2¼ by 4½-in oak keys	⅞-in	3½-in	9	10	12	14

Size of keys	Bolts	Washers	Minimum spacing of keys			
1½ by 3 -in oak keys	¾-in	3-in	11¼-in	11¼-in	9 -in	9 -in
2 by 4 -in oak keys	⅞-in	3-in	15 -in	15 -in	11½-in	11½-in
2¼ by 4½-in oak keys	⅞-in	3-in	17 -in	17 -in	13 -in	13 -in

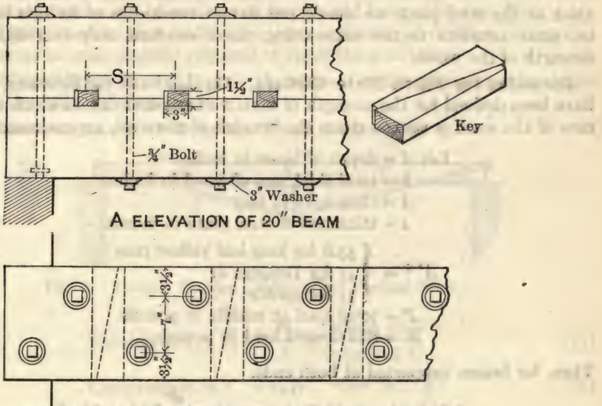
The Breadth or Thickness of Compound Beams should be not less than two-fifths of the depth.

The Number of Keys required is not affected by the length or breadth of the beam, if the beam is figured for the full safe load.

In Spacing the Keys (Figs. 3 and 4) they should not be closer than the minimum spacing given in Table I. For beams loaded at the middle, the spacing of the keys should be uniform from X to Y, Fig. 3, Y being one-eighth the span from the center line. If the distance between the keys, center to cen-

ter, works out less than the minimum spacing, the safe load should be correspondingly reduced or the thickness of the beam increased.

For Beams Uniformly Loaded, the first four or five keys from the end should be spaced for minimum spacing, and the spacing of the remaining keys increased toward the point Y. When the ratio of depth to span is greater than 1 to 16, the inner key may be a little more than one-eighth the span from the center line, for distributed loads. Fig. 3 shows the proper spacing for a 20-in spruce beam of 28-ft span and for a long-leaf yellow pine beam of 30-ft span; and the tabulation below gives the proper spacing of keys for spruce beams of



B PLAN OF 14" X 24" SPRUCE BEAM—36' SPAN

Fig. 4. Details of Keyed and Bolted Wooden Beam

longer spans, figured from the end of the beam in each case. For other woods and spans the spacing should be made as near like these as the fixed conditions will permit. Four examples of spacing are given below. The sizes of bolts and washers to be used are given in Table I. If the beam is not over 10 in wide, the bolts may be arranged as for the spruce beam (Fig. 3); if 12 in wide or over, the bolts should be staggered as shown for the hard-pine beam. In a very wide beam the bolts might be spaced as in detail B, Fig. 4.

Spacing of keys in inches for spruce beams, commencing at end, for uniformly distributed loads:

16-in spruce beam, 32-ft span, 10, 12,	12,	16,	19, 24, 32
20-in spruce beam, 32-ft span, 10, 11½,	11½,	11½,	12, 12, 12, 13, 15, 18, 24
24-in spruce beam, 36-ft span, 13, 15,	15,	15,	15, 16, 18, 20, 30
28-in spruce beam, 36-ft span, 15, 17,	17,	17,	17, 17, 17, 17, 17, 17

2. Flitched Beams or Flitch-Plate Girders

Flitch-Plate Beams (Fig. 5) were at one time much used, but with the present prices of steel it is cheaper and better to use steel beams.

The following explanation and formulas are given, however, for the benefit of those who might have occasion to use a beam of this kind. It has been found in practice that the thickness of the wood should be sixteen times the thickness of the steel. As the steel is so much STIFFER than the wood, we must

proportion the load on the wood so that the latter will bend as much as the steel plate bends: otherwise the whole load might be thrown on the steel plate. The MODULUS OF ELASTICITY of steel is about twenty times that of long-leaf yellow pine; so that a beam of this wood, 1 in wide, will bend twenty times as much as a plate of steel of the same size and under the same load. Hence, if we want this beam to bend just as much as the steel plate, we must put only one-twentieth the load on it. If the wooden beam is sixteen times as thick as the steel plate, we should put sixteen-twentieths of its safe load on it, or, what amounts to the same thing, use a constant only four-fifths of the strength of the wood.

Fig. 5. Flitch-plate Girder

Formulas for Flitch-Plate Girders. On this basis the following formulas have been derived for the strength of FLITCH-PLATE GIRDERS, in which the thickness of the wood is sixteen times the breadth of the steel, approximately:

Let d = depth of beam in inches
b = total thickness of wood in inches
l = clear span in feet
t = thickness of steel plate in inches

$$A'^{*} = \begin{cases} 53.6 \text{ for long-leaf yellow pine} \\ 45 \text{ for Douglas fir} \\ 31 \text{ for spruce} \end{cases}$$

P = total load at middle in pounds
W = distributed load in pounds

Then, for beams supported at both ends,

$$\text{Safe load at middle in pounds} = \frac{d^2}{l}(A'b + 889\,t) \qquad (1)$$

$$\text{Safe distributed load in pounds} = \frac{2\,d^2}{l}(A'b + 889\,t) \qquad (2)$$

$$\text{For distributed load,} \quad d = \sqrt{\frac{Wl}{2\,A'b + 1778\,t}} \qquad (3)$$

$$\text{For load at middle,} \quad d = \sqrt{\frac{Pl}{A'b + 889\,t}} \qquad (4)$$

The bolts should be ¾ in in diameter, and spaced 2 ft on centers. Each end should have two bolts, as in Fig. 5.

Example. What is the safe load, uniformly distributed, for a girder composed of three 4 by 14-in Douglas-fir timbers and two ⅜ by 14-in flitch-plates, with a span of 25 ft?

Solution. By Formula (2),

$$\text{Safe load} = \frac{2 \times 196}{25}(45 \times 12 + 889 \times 3/4) = 18\,922 \text{ lb}$$

3. Trussed Beams and Girders

Use of Trussed Beams and Girders. Whenever we wish to support a floor upon girders having a span of more than 30 ft, we must use a TRUSSED GIRDER, a riveted STEEL-PLATE GIRDER, or two or more STEEL BEAMS. Under

* For commercially seasoned timber and for ideal conditions these values may increase about 30%.

some circumstances and in some parts of the country it may be cheaper or more convenient to use a large wooden girder, and truss it, as in Figs. 6, 7, 8 or 9.

Depth of Trussed Girder. For all these forms it is desirable to give the girders as much depth as the conditions allow; as, the deeper the girder, the smaller the stresses in the pieces.

In the Single-Strut Trussed Girder, we either have two beams, and one rod which runs up between them at the ends, or three beams, and two rods running up between the beams in the same way. The beams should be in one continuous length for the whole span, if they can be obtained in that length. The requisite dimensions of the tie-rod, struts and beams, in any given case, must be determined by first finding the stresses developed in these pieces, and then the areas of cross-sections required to resist these stresses.

For a Single-Strut Truss (Fig. 6), the stresses in the pieces may be determined by the following formulas:

For a Distributed Load *W* Over the Whole Girder (Fig. 6)

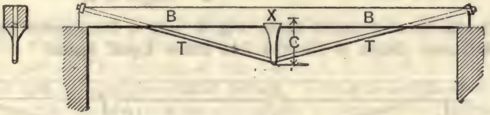


Fig. 6. Trussed Wooden Girder. One Vertical Strut

$$\text{Tension in } T = \frac{W}{2} \times \frac{\text{length of } T}{\text{length of } C} \qquad (5)$$

$$\text{Compression in } C = 5/8\, W. \quad \text{(See Note.)} \qquad (6)$$

$$\text{Compression in } B = \frac{W}{2} \times \frac{\text{length of } B}{\text{length of } C} \qquad (7)$$

Note. When the beam *B* is in one piece, the full length of span. If *B* is jointed over the strut then compression in *C* or tension in *R* = ½ *W*.

For a Concentrated Load *P* Over *C* (Fig. 6)

$$\text{Tension in } T = \frac{P}{2} \times \frac{\text{length of } T}{\text{length of } C} \qquad (8)$$

$$\text{Compression in } C = P$$

$$\text{Compression in } B = \frac{P}{2} \times \frac{\text{length of } B}{\text{length of } C} \qquad (9)$$

For a Girder Trussed as in (Fig. 7), Under a Distributed Load *W* Over the Whole Girder

$$\text{Compression in } S = \frac{W}{2} \times \frac{\text{length of } S}{\text{length of } R} \qquad (10)$$

$$\text{Tension in } R = 5/8\, W. \quad \text{(See Note.)}$$

$$\text{Tension in } B = \frac{W}{2} \times \frac{\text{length of } B}{\text{length of } R} \qquad (11)$$

Note. When the beam *B* is in one piece, the full length of span. If *B* is jointed over the strut then compression in *C* or tension in *R* = ½ *W*.

For a Concentrated Load, *P* at the Middle (Fig. 7)

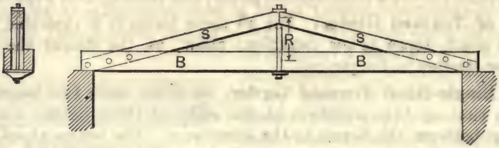

Fig. 7. Trussed Wooden Girder. One Vertical Tie

$$\text{Compression in } S = \frac{P}{2} \times \frac{\text{length of } S}{\text{length of } R} \tag{12}$$

$$\text{Tension in } R = P$$

$$\text{Tension in } B = \frac{P}{2} \times \frac{\text{length of } B}{\text{length of } R} \tag{13}$$

For a Double-Strut Trussed Beam (Fig. 8) with a Distributed Load *W* Over the Whole Girder (Beam *B* Divided into Three Equal Spans)

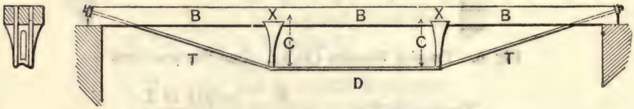

Fig. 8. Trussed Wooden Girder. Two Vertical Struts

$$\text{Tension in } T = \frac{W}{3} \times \frac{\text{length of } T}{\text{length of } C} \tag{14}$$

$$\text{Compression in } C = \frac{W}{3}$$

$$\text{Compression in } B \text{ or tension in } D = \frac{W}{3} \times \frac{\text{length of } B}{\text{length of } C} \tag{15}$$

For a Concentrated Load *P* Over Each of the Struts *C* (Fig. 8)

$$\text{Tension in } T = P \times \frac{\text{length of } T}{\text{length of } C} \tag{16}$$

$$\text{Compression in } C = P$$

$$\text{Compression in } B \text{ or tension in } D = P \times \frac{\text{length of } B}{\text{length of } C} \tag{17}$$

For a Girder Trussed as in Fig. 9, and Under a Distributed Load *W* Over the Whole Girder (Beam *B* Divided into Three Equal Spans)

$$\text{Compression in } S = \frac{W}{3} \times \frac{\text{length of } S}{\text{length of } R} \tag{18}$$

$$\text{Tension in } R = \frac{W}{3}$$

$$\text{Tension in } B \text{ or compression in } D = \frac{W}{3} \times \frac{\text{length of } B}{\text{length of } R} \tag{19}$$

For Concentrated Loads P Applied at Joints 2 and 3 (Fig. 9)

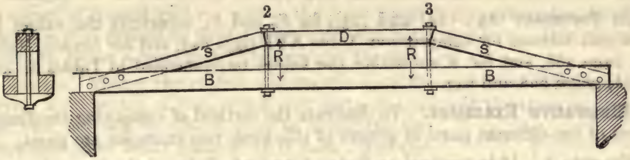

Fig. 9. Trussed Wooden Girder. Two Vertical Ties

$$\text{Compression in } S = P \times \frac{\text{length of } S}{\text{length of } R} \tag{20}$$

$$\text{Tension in } R = P$$

$$\text{Tension in } B \text{ or compression in } D = P \times \frac{\text{length of } B}{\text{length of } R} \tag{21}$$

Trusses constructed as shown in Figs. 8 and 9 should be divided so that the rods R, or the struts C, will divide the lengths of the girder into three equal or nearly equal parts. The lengths of the pieces T, C, B, R, S, etc. should be measured ON THE AXIAL LINES of the pieces. Thus, the length of R should be measured from the CENTER LINE OR AXIS of the tie-beam B to the CENTER LINE OR AXIS of the strut D; and the length of C should be measured from the AXIS of the rod to the AXIS of the strut-beam B.

After determining the stresses in the pieces by these formulas, we may compute the areas of the cross-sections by the following rules:

$$\text{Area of cross-section of a short strut} = \frac{\text{compression in strut}}{S_c} \tag{22}$$

in which S_c for cast iron may be taken at from 13 000 or 14 000 lb per sq in, and for wood as given in Table XVI, page 647.

The size of the long strut D (Fig. 9) should be determined by means of Tables 451 and 452 for wooden columns, Chapter XIV.

The diameters of the tie-rods may be obtained from Table II, page 388.

For the beam B (Figs. 8 and 9) when the load is distributed, we must compute its necessary area of cross-section as a STRUT (Fig. 8) or a TIE (Fig. 9), and also the area of its cross-section, as a BEAM, required to support its load, and use a beam with a section equal to the sum of the two sections thus obtained.

$$\left.\begin{array}{l}\text{Area of cross-section of } B \text{ to resist} \\ \text{tension or compression}\end{array}\right\} = \frac{\text{tension}}{S_t} \text{ or } \frac{\text{compression}}{S_c} \tag{23}$$

In the trusses shown in Figs. 6 and 7, with distributed loads,

$$\text{Breadth of } B \text{ (as a beam)} = \frac{W \times l}{4 \times d^2 \times A} \tag{24}$$

In the trusses shown in Figs. 8 and 9, with distributed loads,

$$\text{Breadth of } B \text{ (as a beam)} = \frac{W \times l}{6 \times d^2 \times A} \tag{25}$$

(Compare Equation (24) and (25) with Equation (11), page 630.)

W denotes the total distributed load in pounds on the girder, and l the length in feet of one section of the beam. When the loads are concentrated over the struts C (Fig. 8) or at the joints R (Fig. 9) then there will be no TRANSVERSE

STRESS on the beams B, and they need be proportioned for the COMPRESSIVE or TENSILE STRESS, only, as the case may be.

In Formulas (23), (24) and (25), for S_c and S_t, substitute the values for safe unit stresses for compression, Table XVI, page 647, and for tension, Table II, page 388, and for A substitute the values recommended in Tables II and XVI, pages 628 and 647.

Illustrative Examples. To illustrate the method of computing the dimensions of the different parts of girders of this kind, two examples are given.

Example 1. It is required to design a trussed girder of the form shown in Fig. 6, for a span of 30 ft. The girders are to be 12 ft on centers, and are to carry a floor loaded with 100 lb per sq ft. The girder consists of three strut-beams B, side by side, and two rods. We can allow the rod T to come two feet below the beams B, and we will assume that the depth of the beams B will be 12 in; then the length of C, measured from the center line of the beam, will be 30 in. The length of B is 15 ft, and by computation, or by scaling, we find the length of T to be 15 ft 2½ in.

Solution. The total load on the girder equals 100 lb multiplied by the span multiplied by the distance of the girders on centers, or, $100 \times 30 \times 12 = 36\,000$ lb. From Formula (5),

$$\text{Tension in } T = \frac{36\,000}{2} \times \frac{182\tfrac{1}{2}\text{ in}}{30\text{ in}} = 109\,500\text{ lb}$$

or 54 750 lb on each of the two rods. For such a large stress it is best to upset the ends of the rods, and allowing 16 000 lb per sq in for steel rods, we find from Table II, Chapter XI, that we must use two 2⅛-in steel rods.

The strut-beam we will make of long-leaf yellow pine. From Formula (7) we find the compressive stress in $B = (36\,000/2) \times (180/30) = 108\,000$ lb. As we are to use three beams side by side, there will be 36 000 lb compression in each beam.

To resist the compression there is required an area of 36 000/1 000 or 36 sq in, which is equal to 3 by 12 in.

From Formula (24) we find the total breadth required to resist the transverse stress $= \dfrac{36\,000 \times 15}{4 \times 144 \times 67} = 14$ in; or each beam must be 4⅔ by 12 in in section to resist the transverse stress, and 3 by 12 in to resist the compressive stress. Consequently each beam must be 7⅔ by 12 in in cross-section.

As this would make the girder very wide, 27¼ in, we will use beams 14 in deep, increasing the depth of the girder 1 in, so that the height on centers will still be 30 in.

The area required to resist the compressive stress will be the same as before, 36 in, but as the beam is 14 in deep the breadth will be only 2.57 in.

The total breadth to resist the transverse stress will be $\dfrac{36\,000 \times 15}{4 \times 196 \times 67} = 10.28$ in, or 3.43 in for each beam. The total breadth for each beam will therefore be 6 in. A beam with a cross-section of 6 by 14 in will meet the requirements. The total width of the girder will then be 22¼ in. The load on $C = \tfrac{5}{8}\,W = 22\,500$ lb, or 11 250 lb over each rod. The theoretical sectional area in square inches necessary to resist this load = 11 250/13 000 for cast iron and 11 250/1 000 for oak. As the struts must be the full width of the girder, however, it will be necessary to make the sectional area much greater than the theoretical requirements. If made of cast iron the strut should be of the shape shown in Fig. 10, and if of oak, of the shape shown in Fig. 11. The cast-iron strut will be the best, but an oak strut will answer.

Example 2. It is required to support a floor over a lecture-room 40 ft wide, by means of trussed girders; and as the room above is to be used for electrical purposes, it is desired to have a truss with very little iron in it. It is decided, therefore, to use a truss such as is shown in Fig. 9.

Solution. Where the girders rest on the wall, there will be brick pilasters having a projection of 6 in, which will make the span of the truss 39 ft, and the rods *RR* will be placed so as to divide the tie-beam into three equal spans of 13 ft each. The tie-beam *B* will consist of two long-leaf yellow pine beams, with the struts *S* coming between them. There are two rods, instead of one, at *RR*, coming down on each side of the struts *S*, and passing through iron castings below the beams *B*, and forming supports for them. The height of the truss from center to center of timbers must be limited to 18 in. The trusses are 8 ft on centers.

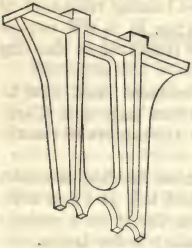

Fig. 10. Cast-iron Strut for Two Tie-rods

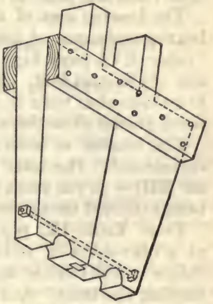

Fig. 11. Wooden Strut for Two Tie-rods

The total floor-area supported by one girder is 8 by 39 ft, or 312 sq ft. The heaviest load to which the floor will be subjected is the weight of the people in the room, for which 75 lb per sq ft is an ample allowance; and the weight of the floor itself is about 100 lb per sq ft. This makes the total weight liable to come on one girder 31 200 lb.

$$\text{Compression in } S\text{, from Formula (18)} = \frac{W}{3} \times \frac{157 \text{ in}}{18 \text{ in}} = 90\,700 \text{ lb}$$

$$\text{Tension in one pair of rods} = \frac{W}{3} = 10\,400 \text{ lb}$$

$$\text{Tension in } B \text{ or compression in } D = \frac{W}{3} \times \frac{156 \text{ in}}{18 \text{ in}} = 90\,130 \text{ lb}$$

As the unsupported length of *D* is greater than that of *S*, a beam that will resist the compression in *D* will be ample for *S*. We find from Table II, Chapter XIV, that it will require a post 10 by 12 in in cross-section to resist the compression in *D*, which is 13 ft in length. The tension in each rod is only 5 200 lb; but as the rods must support a larger washer at the bottom, they are made 1 in in diameter, not upset. The tension in each of the beams *B* is 45 065 lb. This divided by 1 200, the safe unit tensional stress for long-leaf yellow pine = 37.6 sq in, or about 2¾ by 14 in.

The total breadth of the tie-beam to resist the transverse load is found from Formula (25). Assuming 14 in for the depth of *B*

$$\text{Breadth of } B = \frac{31\,200 \times 13}{6 \times 196 \times 67} = 5.15 \text{ in, or about } 2\tfrac{1}{2} \text{ in for each beam}$$

The breadth of each tie-beam must therefore be 2¾ in + 2½ in = 5¼ in. Hence the tie-beams must be 5 by 14 in in section. The girder, therefore, must be built with 10 by 14-in strut-beams and two 5 by 14-in tie-beams, each 42 ft long. The 1-in rods may be cut ½ in into the strut-beams, and ½ in into the tie-

beams, so that the latter will come close against the struts S. The thrust of the strut S is equal to its compressive stress, and a connection between the tie-beams and the struts must be designed that will resist this thrust, which in this case is 90 700 lb. As the inclination of the strut is very slight, there is ample room for bolts. It is best to use bolts which are at least 1½ in in diameter. As they are in double shear, the resistance to shearing of one bolt is 35 340 lb. (See Table IX, page 431.) Steel bolts are used.

The bearing area of a 1½-in bolt in a timber 10 in wide is 15 in. For the bearing resistance of long-leaf yellow pine, we may allow 1 400 lb per sq in (Table XVI, page 647), which will give 21 000 lb as the bearing resistance of one 1½-in steel bolt. As the force to be resisted is 90 700 lb, it will require five 1½-in steel bolts to sustain this bearing pressure, the resistance to shearing being greater than this stress.

The number of bolts required to resist the bending moment must now be determined. The total bending moment to be resisted (see page 434, Chapter XII) = 90 700 times the distance, in inches, between the centers of the tie-beams divided by 12, or $90\,700 \times {}^{15}\!/_{12} = 113\,375$ in-lb.

From Table IX, page 431, we find that the maximum bending moment, at a fiber-stress of 20 000 lb per sq in, for a 1½-in steel bolt is 6 630 in-lb. Hence it will require seventeen 1½-in bolts to resist the thrust in S without bending the bolts. As it is impracticable to put in so many bolts, larger ones must be used. For a 2½-in steel bolt, the maximum bending moment is 30 700 in-lb (Table IX, page 431), and four times this is 122 800 in-lb; hence four 2½-in steel bolts will be sufficient to resist the bending stress, and also the shearing and bearing-stresses. It will be seen from this example that it is much more difficult and expensive to make satisfactory end-joints for girders trussed as in Figs. 7 and 9 than it is for the single and double-strut trusses like those shown in Figs. 6 and 8. The latter forms are to be preferred when the conditions will admit of their use.

These four cases of TRUSSED GIRDERS are but special examples of trusses. The stresses in them may also be determined by the methods explained in Chapter XXVII; and where the divisions of the girder cannot be made uniform, the stresses should be computed by the general methods there explained.

CHAPTER XVIII

STIFFNESS AND DEFLECTION OF BEAMS

BY
CHARLES P. WARREN
ASSISTANT PROFESSOR OF ARCHITECTURE, COLUMBIA UNIVERSITY

1. General Principles of the Deflection of Beams*

Strength and Stiffness. In many structures it is necessary that beams and girders shall be not only STRONG enough but STIFF enough; that is, not only must RUPTURE be prevented, but the beams must not BEND so much as to appear unsightly, or to crack the ceiling. Therefore, in many cases, DEFLECTION, rather than absolute STRENGTH, may become the governing consideration in determining the size of a beam. Unfortunately, there is no method at present of combining the two calculations for STRENGTH and for STIFFNESS in one. A beam properly proportioned for STRENGTH will not bend enough to stress the fibers beyond the ELASTIC LIMIT, but it may in some cases bend more than a due regard for appearances will justify. The distance that a beam bends under a given load is called its DEFLECTION, and its resistance to deflection is called its STIFFNESS.

A General Formula for the Maximum Deflection of any beam under a concentrated or uniformly distributed load not stressed beyond the ELASTIC LIMIT is:

$$\text{Deflection in inches} = \frac{\text{load in pounds} \times \text{cube of span in inches} \times c}{\text{modulus of elasticity} \times \text{moment of inertia}} \quad (1)$$

The values of c are as follows:

For beam supported at both ends, loaded at the middle......	0.021
For beam supported at both ends, uniformly loaded.........	0.013
For cantilever beam, loaded at free end	0.333
For cantilever beam, uniformly loaded......................	0.125

Deflection of Beam with Rectangular Section. By making the proper substitutions in Formula (1), the following formula for a RECTANGULAR beam SUPPORTED AT BOTH ENDS and LOADED AT THE MIDDLE may be derived:

$$\text{Deflection in inches} = \frac{\text{load in pounds} \times \text{cube of span in feet} \times 1\,728}{4 \times \text{breadth} \times \text{cube of depth} \times E} \quad (2)$$

Modulus of Elasticity. From this formula the value of the MODULUS OF ELASTICITY, E, for different materials, has been calculated by accurately measuring the actual deflection of known beams under given loads applied at the middle and then substituting these known quantities in Formula (2).

Simple Formula for Deflection. Formula (2) may be simplified somewhat by representing $1\,728/4E$ by $1/F$, which gives the formula

$$\text{Deflection in inches} = \frac{W \times l^3}{b \times d^3 \times F\dagger} \quad (3)$$

For a DISTRIBUTED LOAD the deflection will be five-eighths of this.

* See, also, in Chapter XVI, formula on page 636 and Table XVI, page 647.

† The constant F corresponds to Hatfield's F, in his treatise on "Transverse Strains."

To Find the Load at the Middle that will cause a GIVEN DEFLECTION, transpose Formula (2) so that the load becomes the left-hand member of the equation. Thus:

$$\text{Load at middle in pounds} = \frac{4 \times \text{breadth} \times \text{cube of depth} \times \text{deflection in in} \times E}{\text{cube of span} \times 1\,728} \qquad (4)$$

Limit of Deflection. In order that this formula may be of use in determining the maximum load which may be placed upon a beam, the LIMIT OF THE DEFLECTION must in some way be fixed. This is generally done by making it a certain proportion of the span.

Allowable Deflection of Floor-Beams. Tredgold and other authorities state that if a floor-beam deflects more than ONE-FORTIETH OF AN INCH FOR EVERY FOOT OF SPAN, it is liable to crack the ceiling on the under side; and hence this is the limit which is often set for the deflection of beams in first-class buildings.

Formulas for Deflection of Floor-Beams. If the length in feet divided by 40 is substituted for the deflection in inches, Formula (4) becomes

$$\text{Load at the middle} = \frac{\text{breadth} \times \text{cube of depth} \times e}{\text{square of span in feet}} \qquad (5)$$

in which $e = \dfrac{E}{17\,280}$

Most engineers and architects, however, think that ONE-THIRTIETH OF AN INCH PER FOOT OF SPAN, that is, $1/360$ of the span, is not too much to allow for the deflection of floor-beams, as a floor is seldom subjected to its full estimated load, and then only for a short time.

Table I. Values of Constants for Stiffness or Deflection on Beams*

Material	E	$F = \frac{E}{432}$	$e = \frac{E}{17\,280}$	$e_1 = \frac{E}{12\,960}$
Cast iron	15 000 000	34 722	862	1 157
Wrought iron	26 000 000	60 000	1 500	2 000
Steel	29 000 000	67 130	1 678	2 238
Ash	1 482 000	3 430	87	114
California redwood	700 000	1 620	40	54
Cedar	700 000	1 620	40	54
Chestnut	900 000	2 080	52	69
Cypress	900 000	2 080	52	69
Douglas fir	1 500 000	3 472	87	116
Hemlock	900 000	2 080	52	69
Long-leaf yellow pine	1 500 000	3 472	87	116
Maple	1 902 000	4 400	110	146
Norway pine	1 100 000	2 546	64	85
Short-leaf yellow pine	1 200 000	2 777	69	92
Spruce	1 200 000	2 777	69	92
White oak	1 500 000	3 472	87	116
White pine	1 000 000	2 315	58	77

E = modulus of elasticity, pounds per square inch;
F = constant for deflection of beam, supported at both ends, and loaded at the middle;
e = constant, allowing a deflection of one-fortieth of an inch per foot of span;
e_1 = constant, allowing a deflection of one-thirtieth of an inch per foot of span.

* See, also, in Chapter XVI, formula on page 636 and Table XVI, page 647.

If this ratio is adopted, the CONSTANT FOR DEFLECTION becomes

$$e_1 = \frac{E}{12\,960}$$

Constants for Stiffness or Deflection of Beams. In either of the above cases it is evident that the values used for E, F, e, or e_1, should be derived from tests on timbers of the same size and quality as those to be used. The values for the various woods given in the following table have been adopted by the editors after careful comparison with the results of numerous tests on large timbers and with values given by different authorities. The editors believe that they are perfectly reliable for first-class merchantable timber.

2. Formulas for Loads, Based Upon the Stiffness of Beams

Safe Loads for Limited Deflections for Rectangular Beams. Knowing the deflection caused by a load concentrated at the middle of a beam, and the RATIO OF OTHER DEFLECTIONS, caused by different modes of loading and supporting, formulas for Cases I to VIII, Figs. 1 to 8, considered under the strength of RECTANGULAR BEAMS (Chapter XVI), can be easily deduced. These cases, arranged in a different order, are:

For Beams Supported at Both Ends*

Load at the middle

$$\text{Safe load} = \frac{\text{breadth} \times \text{cube of depth} \times e_1}{\text{square of span}} \qquad (6)$$

or,

$$\text{Breadth} = \frac{\text{load} \times \text{square of span}}{\text{cube of depth} \times e_1} \qquad (7)$$

Load at a point other than at the middle, *m* and *n* being the segments into which the beam is divided

$$\text{Safe load} = \frac{\text{breadth} \times \text{cube of depth} \times \text{square of span} \times e_1}{16 \times m^2 \times n^2} \qquad (8)$$

or,

$$\text{Breadth} = \frac{\text{load} \times m^2 \times n^2 \times 16}{\text{cube of depth} \times \text{square of span} \times e_1} \qquad (9)$$

Load uniformly distributed

$$\text{Safe load} = \frac{8 \times \text{breadth} \times \text{cube of depth} \times e_1}{5 \times \text{square of span}} \qquad (10)†$$

or,

$$\text{Breadth} = \frac{5 \times \text{load} \times \text{square of span}}{8 \times \text{cube of depth} \times e_1} \qquad (11)$$

Inclined beam, loaded at the middle‡

$$\text{Safe load} = \frac{\text{breadth} \times \text{cube of depth} \times e_1}{\text{span} \times \text{horizontal distance between supports}} \qquad (12)$$

or,

$$\text{Breadth} = \frac{\text{load} \times \text{span} \times \text{horizontal distance between supports}}{\text{cube of depth} \times e_1} \qquad (13)$$

* In Formulas (6) to (17) the breadth and depth are to be taken in inches, and the length or span in feet. The load is always in pounds.

The values given in either of the last two columns of Table I may be used for e or e_1, according to the degree of stiffness desired, but the values e_1 in the last column are ample under ordinary conditions.

† See, also, formula in Chapter XVI, page 636.

‡ Tredgold's Elements of Carpentry, page 65.

For Beams Fixed at One End, or Cantilever Beams

Load at the free end

$$\text{Safe load} = \frac{\text{breadth} \times \text{cube of depth} \times e_1}{16 \times \text{square of span}} \tag{14}$$

or,

$$\text{Breadth} = \frac{16 \times \text{load} \times \text{square of span}}{\text{cube of depth} \times e_1} \tag{15}$$

Load uniformly distributed

$$\text{Safe load} = \frac{\text{breadth} \times \text{cube of depth} \times e_1}{6 \times \text{square of span}} \tag{16}$$

or,

$$\text{Breadth} = \frac{6 \times \text{load} \times \text{square of span}}{\text{cube of depth} \times e_1} \tag{17}$$

Note. When the span in feet is less than the depth in inches, the beams should not be calculated by the formulas for STIFFNESS, but by those for HORIZONTAL SHEAR. (See Chapter XVI, page 635.)

3. Relative Stiffness of Beams

Beam supported at both ends and loaded at the middle	1
Beam supported at both ends and uniformly loaded	8/5
Beam fixed or restrained at both ends and loaded at the middle	4
Beam fixed or restrained at both ends and uniformly loaded	8
Cantilever beam loaded at the free end	1/16
Cantilever beam uniformly loaded	1/8

The Stiffest Rectangular Beam containing a given amount of material is that in which the ratio of depth to breadth is as 10 is to 6; hence, in designing beams, the depth and breadth should be made to approach as near this ratio as is practicable.

Example 1. What is the greatest distributed load that an 8 by 10 in white-pine girder, 20 ft in span, will support, without deflecting at the center more than one-thirtieth of an inch per foot of span?

Solution. This girder comes under the case of a beam supported at both ends and loaded with a uniformly distributed load, and hence should be calculated by Formula (10). Substituting the given dimensions in Formula (10),

$$\text{Safe load} = \frac{8 \times 8 \times 1\,000 \times 77}{5 \times 400} = 2\,464 \text{ lb}$$

Example 2. What should be the dimensions of a long-leaf yellow-pine beam, 10 ft in span, to support a concentrated load of 4 250 lb at the middle without deflecting more than one-third of an inch at the center?

Solution. A deflection of one-third of an inch in a span of 10 ft is in the proportion of one-thirtieth of an inch per foot of span; and as the load is concentrated at the middle, Formula (7) should be used, with e_1, the value given in the fourth column opposite long-leaf yellow pine.

Formula (7) gives the dimensions of the breadth, but in order to obtain it, a value for the depth must first be assumed. For such a short span, 10 inches would seem to be a proper depth.

Substituting in Formula (7)

$$\text{Breadth} = \frac{4\,250 \times 100}{1\,000 \times 116} = 3.6 \text{ in}$$

Hence it will be necessary to use a 4 by 10-in beam. As the span of this beam in feet is the same as its depth in inches, it should be tested to see if it meets the requirements for strength also. From Table XII, page 643, it is found that the safe distributed load for a 1 by 10-in beam, 10 ft in span, is 1 333 lb, and for a 4 by 10-in beam the safe load would be four times as much, or 5 332 lb. The load in this example, however, is applied at the middle; hence the safe distributed load must be divided by 2, which gives 2 666 lb for the safe load at the middle. As this is much less than the load to be carried, the size of the beam should be increased to 4 by 16 in. In general it is not safe to use the FORMULAS FOR STIFFNESS when the span in feet does not exceed the depth in inches.

Example 3. What is the largest load that an inclined spruce beam 8 by 12 in in cross-section and 16 ft in length between the supports will carry at the middle, consistent with stiffness, the horizontal distance between the supports being 14 ft?

Solution. Formula (12) is the one to be used in this case. Assuming the limit of deflection at one-thirtieth of an inch per foot of span, the value of e_1 is found opposite spruce in the last column of Table I. Making the proper substitutions,

$$\text{Safe load} = \frac{8 \times 1\,728 \times 92}{16 \times 14} = 5\,678 \text{ lb}$$

4. Cylindrical Beams

Formulas. The formulas for beams with SQUARE CROSS-SECTIONS may be used for beams with CIRCULAR CROSS-SECTIONS, if $1.7 \times e$ is substituted for e. That is, other conditions being equal, a CYLINDRICAL BEAM bends or deflects 1.7 times as much as a beam the cross-section of which is the square circumscribing the circular cross-section of the cylindrical beam.

5. Safe Loads for Wooden Beams for a Given Deflection

Use of Tables and Formulas. Tables VII to XV, inclusive, pages 638 to 646, giving the SAFE LOADS FOR BEAMS, give, also, the maximum loads for beams, 1 in thick, that will cause a DEFLECTION not exceeding 1/360 of the span, that is, 1/30 in per foot of span. Where two loads are given for any span or depth the upper load is calculated for STRENGTH and the lower load for DEFLECTION. Where one load is given the calculation is for strength, as the calculation for deflection in those particular beams would give an excessive load (Example 2). To find the corresponding load for any thickness, multiply the load given in the table by the breadth of the beam in inches. Suppose, for example, that it is required to find the greatest distributed load that an 8 by 10-in white-pine girder, 20 ft in span, will support, without deflecting at the center more than one-thirtieth of an inch per foot of span. Referring to Table VIII, page 639, giving the safe loads in pounds for white-pine beams, two values are found opposite the 20-ft span, 389 and 308, the latter being the safe load for deflection. The safe load, therefore, for an 8 by 10-in girder will be eight times, or $308 \times 8 = 2\,464$ lb, which agrees with the safe load for the same girder calculated for deflection by Formula 10, Example 1.

6. Nominal and Standard Sizes of Wooden Beams

Conversion Factors for Wooden Beams of Standard Size. Table II may be used for beams that measure less than the NOMINAL DIMENSIONS. DRESSED BEAMS, and in many localities floor-joists carried in stock, are more

or less SCANT of the nominal dimensions, and for such joists a reduction in the safe load must be made to correspond to the reduction in size. The DRESSED SIZES are generally ¼ in scant up to 4 in in breadth, above which they are ½ in scant; while in depth they are all generally ½ in less than the NOMINAL SIZES. The safe loads may be obtained by multiplying the safe loads as given in Tables VII to XV, pages 638 to 646, by the FACTORS given in the following table:

Table II. Conversion Factors for Beams of Commercial or Standard Sizes

Cross-sections of beams in inches	Factors	Cross-sections of beams in inches	Factors
1¾×5½	1.47	1¾×11½	1.61
2¾×5½	2.31	2¾×11½	2.53
1¾×6½	1.51	1¾×13½	1.63
2¾×6½	2.51	2¾×13½	2.56
1¾×7½	1.54	1¾×15½	1.65
2¾×7½	2.42	2¾×15½	2.58
1¾×9½	1.58	1¾×17½	1.65
2¾×9½	2.48	2¾×17½	2.60

Example 4. What is the safe load for a 2¾ by 13½-in spruce beam, 18-ft span?

Solution. From Table VIII, page 639, the safe load for a 1 by 14-in beam is 847 lb. Multiplying this by 2.56 the product is 2 168 lb, the safe distributed load for a beam 2¾ by 13½ in in cross-section. For a full, "nominal" size, 3 by 14-in, the safe load would be 2 541 lb.

7. Deflection of Steel Beams

General Formula. The DEFLECTION of any steel beam may be found by means of Formula (1), page 663.

Example 5. It is required to determine the deflection of a 12-in 31.5-lb beam, 20 ft in span, under its maximum uniformly distributed load of 9.59 tons.

Solution. The load in pounds = 9.59 tons × 2 000 = 19 180 lb; the span in inches = 20 ft × 12 = 240 in; *c*, for a beam supported at both ends and uniformly loaded, from the values given under Formula (1), is 0.013; *E*, for steel is 29 000 000 lb per sq in (Table I, page 664); and the moment of inertia, from the properties of steel **I** beams, page 355, is 215.8. Substituting these values in Formula (1), page 663,

$$\text{Deflection in inches} = \frac{19\,180 \times 240^3 \times 0.013}{29\,000\,000 \times 215.8} = 0.551 \text{ in}$$

The allowable deflection is 1/30 of an inch per foot of span, or 20/30 = 0.666 in.

Coefficients of Deflection. In order to save the time required to use the DEFLECTION-FORMULA, COEFFICIENTS OF DEFLECTION have been worked out for different spans and are given in Table III.

Table III. Coefficients of Deflection for Uniformly Distributed Loads*

Span in feet	Fiber-stress, pounds per square inch			Span in feet	Fiber-stress, pounds per square inch		
	16 000	14 000	12 500		16 000	14 000	12 500

To find the deflection in inches of a section SYMMETRICAL ABOUT THE NEUTRAL AXIS, such as the section of an **I** beam, channel, zee, etc., divide the coefficient in the table corresponding to the given span and fiber-stress by the depth of the section in inches. To find the deflection in inches of a section NOT SYMMETRICAL ABOUT THE NEUTRAL AXIS, such as the section of an angle, tee, etc., divide the coefficient corresponding to the given span and fiber-stress by twice the distance of the extreme fiber from the neutral axis, obtained from the tables of Chapter X. To find the deflection in inches of a section FOR ANY OTHER FIBER-STRESS than the fiber-stresses given, multiply this fiber-stress by any of the coefficients in Table III, for the given span, and divide by the fiber-stress corresponding to the coefficient used.

Example 6. Required the deflection of a 10-in 25-lb beam of 10-ft span, under its maximum distributed load of 13 tons, the fiber-stress being taken at 16 000 lb per sq in. Table III gives 1.655 as the deflection-coefficient, and dividing this by 10, the depth of the beam in inches, the result is $1.655/10 = 0.1655$, for the deflection at the middle. By Formula (1), page 663, the deflection for the same beam, span, and load $= \dfrac{26\,000 \times 1\,728\,000 \times 0.013}{29\,000\,000 \times 122.1} = 0.1649$ in, the

two results being nearly identical. For the same beam, a span of 18 ft and a load of 7.2 tons, the deflection by the table is 0.5363 in; and by Formula (1), 0.5328 in, practically the same result.

Safe Loads and Deflection. In the tables of Chapter XV, giving the safe loads for I beams, channels and rolled beams of other cross-sections, the loads given are for the SAFE LIMIT OF DEFLECTION; and the safe loads, also, are given which will cause deflections of more than 1/360 of the span-length in inches.

Lateral Deflection of Beams.* When the unbraced length exceeds ten times the width, the tabular safe loads should be reduced in accordance with the ratios given in the following table in order to insure that the stresses in the compression-flanges should not exceed the allowed safe unit stress:

Length of span	Allowable safe load	Length of span	Allowable safe load
5 × flange-width	Full tabular load	25 × flange-width	71.9% tabular load
10 × flange-width	Full tabular load	30 × flange-width	62.5% tabular load
15 × flange-width	90.6% tabular load	35 × flange-width	53.1% tabular load
20 × flange-width	81.2% tabular load	40 × flange-width	43.8% tabular load

"In addition to this lateral deflection which is induced within the beam by the action of pure bending-stresses, lateral deflection may be induced by the thrust of floor-arches or other loading acting on an axis perpendicular to the line of principal bending-stress. The thrust of these arches should either be neutralized by tie-rods, or the safe carrying capacity of the beam should be computed in accordance with the general formulas of flexure to provide for the combined stresses due to the action of both vertical and horizontal forces; that is to say, the safe loads should be figured around both the axes 1-1 and 2-2, and the unit stress computed so as not to exceed 16 000 lb per sq in."

CHAPTER XIX

STRENGTH AND STIFFNESS OF CONTINUOUS GIRDERS

BY

CHARLES P. WARREN

ASSISTANT PROFESSOR OF ARCHITECTURE, COLUMBIA UNIVERSITY

1. General Considerations

Continuous Versus Single-Span Girders. A CONTINUOUS GIRDER is one resting upon three or more supports, as distinguished from a SIMPLE GIRDER which rests upon two supports. Continuous girders, except in reinforced-concrete construction, and in some types of grillage-foundations, are of rare occurrence in building-construction. While in almost every building of importance it is necessary to employ girders resting upon piers or columns, placed from 15 to 20 ft apart, and while in many cases steel girders could conveniently be obtained which would span two and even three of the bays between the supports, they are practically limited to one-story buildings, because in tall buildings it is better construction to have the vertical rather than the horizontal supports continuous. Many different opinions are held as to the RELATIVE STRENGTH and STIFFNESS of continuous and non-continuous girders, and different formulas have been proposed from time to time; but in this chapter the mathematical discussions will not be given.*

Continuous Girders and Overhanging Girders. In all CONTINUOUS GIRDERS, the end-spans (Fig. 2) are somewhat in the condition of a SIMPLE GIRDER with ONE OVERHANGING END, while the other spans are somewhat in the condition of a SIMPLE GIRDER with TWO OVERHANGING ENDS. At each intermediate support there is a NEGATIVE BENDING MOMENT, the effect of which is to reduce the bending moments between the supports.

2. Supporting Forces or Reactions of Continuous Girders

Continuous Girder of Two Equal Spans. Concentrated Load at the Middle of Each Span. If a girder of two spans, each equal to l (Fig. 1), be loaded at the middle of the left span with P lb, and at the middle of the right span with P_1 lb, the reaction at the support R_1 is determined by the formula

$$R_1 = \frac{13\,P - 3\,P_1}{32} \tag{1}$$

the reaction at the support R_2 by

$$R_2 = 1\tfrac{1}{16}\,(P + P_1) \tag{2}$$

and the reaction at the support R_3 by the formula

$$R_3 = \frac{13\,P_1 - 3\,P}{32} \tag{3}$$

* For the derivation of the following formulas, see an article by F. E. Kidder on this subject, in Van Nostrand's Engineering Magazine, July, 1881.

If $P = P_1$, then each of the end-supports must support $\frac{5}{16} P$ and the middle support $\frac{22}{16} P$. If the girder is cut so as to make two girders of one span each, then the end-supports will carry $\frac{1}{2} P$ or $\frac{8}{16} P$, and the middle support $\frac{16}{16} P$. Hence, it is seen that by using the continuous girder of three spans, the reactions of the end-supports are diminished, while the reaction at the middle support is increased.

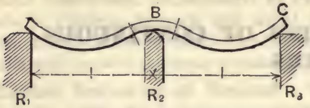

Fig. 1. Continuous Girder of Two Spans

Continuous Girder of Two Spans. Uniformly Distributed Load Over Each Span (Fig. 1). Load over each span equals w lb per unit of length. Let l be the length of the left span and l_1 the length of the right span. Reaction of left support

$$R_1 = \frac{w}{2}\left[l - \frac{l_1^3 + l^3}{4\,l\,(l + l_1)}\right] \tag{4}$$

Reaction of middle support,

$$R_2 = w\,(l + l_1) - R_1 - R_3 \tag{5}$$

Reaction of right support

$$R_3 = \frac{w}{2}\left[l_1 - \frac{l_1^3 + l^3}{4\,l_1\,(l + l_1)}\right] \tag{6}$$

When both spans are equal to l, the reaction of each end-support is $\frac{3}{8}\,wl$, and of the middle support $\frac{5}{4}\,wl$; hence the girder, by being continuous, reduces the reactions of the end-supports, and increases that of the middle support $\frac{1}{4}$, or 25%.

Continuous Girder of Three Equal Spans. Concentrated Load of P Pounds at the Middle of Each Span (Fig. 2).

Reaction of either abutment

$$R_1 = R_4 = \frac{7}{20}\,P \tag{7}$$

Reaction of either middle support

$$R_2 = R_3 = \frac{23}{20}\,P \tag{8}$$

or the reactions of the two end-supports are $\frac{3}{10}$ less, and those of the two middle supports $\frac{3}{20}$ greater than they would have been had three separate girders of the same cross-section been used, instead of one continuous girder.

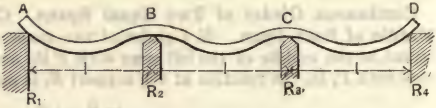

Fig. 2. Continuous Girder of Three Spans

Continuous Girder of Three Equal Spans. Uniformly Distributed Load Over Each Span (Fig. 2). The load per unit of length is w lb.

Reaction of either end-support

$$R_1 = R_4 = \frac{2}{5}\,wl \tag{9}$$

Reaction of either middle support

$$R_2 = R_3 = \frac{11}{10}\,wl \tag{10}$$

Hence the reactions of the end-supports are $\frac{1}{5}$ less, and of the middle supports $\frac{1}{10}$ more, than if the girder were not continuous.

3. Bending Moments of Continuous Girders

Strength of Continuous Girders. The STRENGTH of a girder depends upon its material and the shape of its cross-section, and also upon the disposition of the external loads imposed upon it. The latter give rise to the BENDING MOMENTS, which are measures of the tendencies of the external forces, such as the loads and the supporting forces, to bend or to break the girder. It is the difference in the numerical values of these BENDING MOMENTS which causes the difference in the FLEXURAL STRENGTH of continuous and non-continuous girders of the same cross-section.

Continuous Girders of Two Spans. When a beam is at the point of breaking by flexure, the FLEXURE-FORMULA, $M = SI/c$, is frequently used to calculate a NOMINAL UNIT STRESS developed in the beam; and when the beam has a rectangular cross-section the formula takes the form (see page 635)

$$\text{Maximum bending moment} = \frac{\text{Modulus of rupture}^{*} \times \text{breadth} \times \text{square of depth}}{6} \qquad (11)$$

In order that the beam may carry its load with perfect safety, the breaking-load must be divided by a proper FACTOR OF SAFETY. Hence, if the MAXIMUM BENDING MOMENT of a beam can be found under any conditions, the required dimensions of the beam can easily be determined from Formula (11). (See Table I, page 557, for the safe values of the FIBER-STRESSES.) The greatest bending moment for a continuous girder of two spans is almost always over the middle support, and is a MINUS BENDING MOMENT, if the plus sign is given to the maximum bending moments between the supports. It is the NUMERICAL VALUE only, however, that is considered.

Continuous Girder of Two Spans. Distributed Load over Each Span. The greatest bending moment in a continuous girder of two spans, l and l_1 (Fig. 1), loaded with a uniformly distributed load of w lb per unit of length is over the middle support and is

$$\text{Maximum bending moment} = \frac{wl^3 + wl_1^3}{8\,(l + l_1)} \qquad (12)$$

When $l = l_1$, or both spans are equal,

$$\text{Maximum bending moment} = wl^2/8 \qquad (12a)$$

which is the same as the maximum bending moment of a beam supported at both ends and uniformly loaded over its whole length. Hence a continuous girder of two spans uniformly loaded is no stronger as far as flexure is concerned than if non-continuous.

Continuous Girder of Two Equal Spans. Concentrated Load at the Middle of Each Span. The greatest bending moment in a continuous girder of two equal spans, each of length l, loaded with P lb at the middle of one span, and with P_1 lb at the middle of the other, is

$$\text{Maximum bending moment} = \tfrac{3}{32}\, l\,(P + P_1) \qquad (13)$$

* The modulus of rupture is equal to the ultimate flexural unit stress developed in a beam when the bending moment is great enough to cause failure, and is expressed in pounds per square inch. It usually lies between the ultimate unit compressive strength and the ultimate unit tensile strength of the material. (See, also, Chapter XV, page 556.) It is to be noted, that the flexure-formula $M = SI/c$ is not really applicable to beams of materials for which the stresses are not proportional to the deformation, nor to non-homogeneous beams, nor to beams under stresses greater than the elastic limit of the material.

When $P = P_1$, or the two loads are equal, this becomes

$$\text{Maximum bending moment} = \tfrac{3}{16} Pl \tag{13a}$$

or ¼ less than its value when the beam is cut at the middle support.*

Continuous Girder of Three Spans. Uniformly Distributed Load Over Each Span. The greatest bending moment in a continuous girder of three spans loaded with a uniformly distributed load of w lb per unit of length, the length of each end-span being l_1 and of the middle span l, is at either of the middle supports, and is determined by the formula

$$\text{Maximum bending moment} = \frac{wl^3 + wl_1^3}{4\,(3\,l + 2\,l_1)} \tag{14}$$

When the three spans are equal, this becomes

$$\text{Maximum bending moment} = wl^2/10 \tag{14a}$$

or ⅕ less than what it would be were the beam not continuous.

Continuous Girder of Three Equal Spans. Concentrated Load of *P* Pounds at the Middle of Each Span. The greatest bending moment in a continuous girder of three equal spans, each of a length l, and each loaded at the middle with P pounds, is

$$\text{Maximum bending moment} = \tfrac{3}{20} Pl \tag{15}$$

or ⅖ less than that of a non-continuous girder.

4. Deflection of Continuous Girders

Continuous Girder of Two Equal Spans. Uniformly Distributed Load Over Each Span. The greatest deflection of a continuous girder of two equal spans loaded with a uniformly distributed load of w lb per unit of length is

$$\text{Maximum deflection} = 0.005416\, wl^4/EI \tag{16}$$

in which E is the MODULUS OF ELASTICITY and I the MOMENT OF INERTIA of the cross-section of the beam. The greatest deflection of a similar beam supported at both ends and uniformly loaded is

$$\text{Maximum deflection} = 0.013020\, wl^4/EI$$

Hence the deflection of the continuous girder is only about ⅖ that of a non-continuous girder. The greatest deflection of a continuous girder of two spans is not at the middle of either span, but between the middle point of a span and one of the abutments. The greatest deflection of a continuous girder of two equal spans, loaded at the middle of one span with a load of P lb, and at the middle of the other with P_1 lb, is, for the span with the load, P

$$\text{Maximum deflection} = \frac{(23\,P - 9\,P_1)\,l^3}{1\,536\,EI} \tag{17}$$

for the span with load P_1

$$\text{Maximum deflection} = \frac{(23\,P_1 - 9\,P)\,l^3}{1\,536\,EI} \tag{17a}$$

When both spans have the same load

$$\text{Maximum deflection} = \tfrac{7}{768}\, Pl^3/EI \tag{17b}$$

* In this continuous beam the maximum bending moment is the minus bending moment over the middle support and in each of the two simple beams the maximum bending moment is a plus bending moment and is between two supports.

The greatest deflection of a simple beam supported at both ends and loaded at the middle with P lb is

$$\text{Maximum deflection} = Pl^3/48\,EI$$

or the deflection of the continuous girder is only 7/16 that of a non-continuous one.

Continuous Girder of Three Equal Spans. Uniformly Distributed Load Over Each Span.

The load per unit of length is w lb.

$$\text{Greatest deflection at the middle of middle span} = 0.00052\,wl^4/EI \qquad (18)$$

$$\text{Greatest deflection in the end-spans} = 0.006884\,wl^4/EI \qquad (19)$$

Hence the maximum deflection of the continuous girder is only about ½ that of a non-continuous girder.

Continuous Girder of Three Equal Spans. Concentrated Load *P* at the Middle of Each Span.

$$\text{Greatest deflection at the middle span} = \tfrac{1}{480}\,Pl^3/EI \qquad (20)$$

$$\text{Greatest deflection at the middle of end-spans} = \tfrac{11}{960}\,Pl^3/EI \qquad (21)$$

Hence the maximum deflection of the continuous girder is only 11/20 of that of the non-continuous girder.

5. Notes on Reactions, Strength and Stiffness of Continuous Girders

Supports and Reactions of Continuous and Non-Continuous Girders. From the foregoing, some conclusions can be drawn which will be of use in deciding whether it is best in any case to use a CONTINUOUS or a NON-CONTINUOUS GIRDER. From the formulas given for the reactions of the supporting forces in the different cases of continuous girders it is seen that the end-supports do not bear as much of the load as they do when the girders are non-continuous. The difference is added to the reactions of the other supports. This might be of advantage in a building in which the girders run across the building, and have their outside ends supported by the side walls and their inside ends by piers or columns. In this case, by using continuous girders, part of the load could be taken from the walls and transferred to the piers or columns. But in cases of this kind, the vibration may have to be considered. If the building is a mill or factory in which the girders support machines, any vibration in the middle span of the girder is carried to the side walls if the girder is continuous; while if non-continuous girders are used, with their ends an inch or so apart, little or no vibration is carried to the side walls from the middle span. In all cases of important construction the supporting forces should be carefully considered.

Relative Strength of Continuous and Non-Continuous Girders. As the RELATIVE STRENGTH of continuous and non-continuous girders of the same cross-section, material and spans, and loaded in the same way, is proportional to their maximum BENDING MOMENTS, the strength of a continuous girder can be calculated, from the formula for its MAXIMUM BENDING MOMENT. From the values given for these bending moments for the various cases considered, it is seen that the parts of the girder most stressed are those which come over the middle supports. It is seen, also, that, except in the single case of a girder of two spans uniformly loaded, the strength of a continuous girder is greater than that of a non-continuous girder. But the gain in strength in some instances is not very great, although it is generally enough to pay for making the girder continuous.

Relative Stiffness of Continuous and Non-Continuous Girders. The STIFFNESS of a girder varies inversely as its DEFLECTION; that is, the less the deflection under a given load the stiffer the girder. From the values given for the MAXIMUM DEFLECTION of continuous girders, it is evident that the STIFFNESS of a girder is increased by making it continuous; and this is usually the principal advantage in the use of continuous girders. It sometimes happens in building-construction that it is necessary to use beams and girders of much greater strength than is required to carry the superimposed load, because the deflections of smaller beams or girders would be too great. But if continuous girders are used they may be made of just the size required for strength, because their deflections are less. Where great stiffness is required, therefore, continuous beams or girders should be used if possible, as in the case of grillage-girders. (See Example 3, page 679.)

6. Formulas for the Strength and Stiffness of Continuous Girders

Girders of Rectangular Cross-Section. For convenience, the proper formulas for calculating the strength and stiffness of continuous girders of rectangular cross-section are given. The formulas for strength are deduced from the flexure-formula $M = SI/c$, modified for the rectangular section of breadth b and depth d.

$$\text{Bending moment} = \frac{b \times d^2 \times S}{6} \tag{22}$$

in which S is the safe unit fiber-stress. This is eighteen times the coefficient A * of Table II, page 628.

STRENGTH. **Continuous Girder of Two Equal Spans. Uniformly Distributed Load Over Each Span.**

$$\text{Breaking-load}\,\dagger = \frac{2 \times b \times d^2 \times A^*}{l} \tag{23}$$

where b denotes the breadth and d the depth of the girder in inches, and l the length of one span, in feet. The values of the constant A are three times the values given in Table II, page 628. For long-leaf yellow pine, 201; for Douglas fir, 168; chestnut, 132; and for spruce and white pine, 117 lb per sq in, are recommended for the values of A in these formulas.

Continuous Girder of Two Equal Spans. Concentrated Load at the Middle of Each Span.

$$\text{Breaking-load} = 4/3 \times \frac{b \times d^2 \times A}{l} \tag{24}$$

Continuous Girder of Three Equal Spans. Uniformly Distributed Load Over Each Span.

$$\text{Breaking-load} = 5/2 \times \frac{b \times d^2 \times A}{l} \tag{25}$$

Continuous Girder of Three Equal Spans. Concentrated Load at the Middle of Each Span.

$$\text{Breaking-load} = 5/3 \times \frac{b \times d^2 \times A}{l} \tag{26}$$

* See, also, Table I, page 557, and Table XVI, page 647, for safe fiber-stresses.

† Breaking-load in pounds in all cases.

STIFFNESS. **Continuous Girder of Two Equal Spans. Uniformly Distributed Load Over Each Span.**

The following formulas give the loads which the beams will support without deflecting more than one-thirtieth of an inch per foot of span.

$$\text{Load on one span} = \frac{b \times d^3 \times e_1}{0.26 \times l^2} \qquad (27)$$

Continuous Girder of Two Equal Spans. Concentrated Load at the Middle of Each Span.

$$\text{Load on one span} = {}^{16}\!/_{7} \times \frac{b \times d^3 \times e_1}{l^2} \qquad (28)$$

Continuous Girder of Three Equal Spans. Uniformly Distributed Load Over Each Span.

$$\text{Load on one span} = \frac{b \times d^3 \times e_1}{0.33 \times l^2} \qquad (29)$$

Continuous Girder of Three Equal Spans. Concentrated Load at the Middle of Each Span.

$$\text{Load on one span} = {}^{20}\!/_{11} \times \frac{b \times d^3 \times e_1}{l^2} \qquad (30)$$

The value of the constant e_1 is obtained by dividing the MODULUS OF ELASTICITY by 12 960; and, for the three woods most commonly used as beams, the following values may be taken:

Long-leaf yellow pine, 116; white pine, 77; spruce, 92; Douglas fir, 116. (For other woods, see Table I, page 664.)

For Continuous Steel Beams the requisite size may be found by first computing the MAXIMUM BENDING MOMENT, by means of Formulas (12) to (15), and then selecting a beam that has a

$$\text{SECTION-MODULUS} = \frac{3 \times \text{maximum bending moment in ft-lb}}{4\,000} \qquad (31)$$

Values for the SECTION-MODULI for the different shapes of rolled steel used as beams are given in the tables in Chapter X.

Example 1. What steel beam should be used to support two loads of 16 000 lb each, concentrated at the middle of two spans of 10 ft each, the beam being continuous?

Solution. Formula (13*a*) gives the maximum bending moment as $\frac{3}{16}$ *Pl*, or 30 000 ft-lb. Therefore, from Equation (31), a beam having a section-modulus equal to $3 \times 30\,000/4\,000$ or 22.5 should be used. From the Table IV, page 355, it is found that a 9-in 30-lb beam has a section modulus of 22.6, and a 10-in 25-lb beam a section modulus of 24.4. Either of these beams will therefore answer, the 10-in beam being the cheaper, however, and also the stiffer.

Example 2. A steel beam continuous over three spans is required to support a uniformly distributed load of 1 000 lb per lin ft. The two end-spans are 12 ft each, and the middle span 10 ft. What should be the size and the weight of the beam used?

Solution. The maximum bending moment is found by Formula (14), and is

$$\frac{1\,000 \times 1\,000 + 1\,000 \times 1\,728}{4\,(30 + 24)} = 12\,630$$

The section-modulus, by Equation (31), must equal $3 \times 12\,630/4\,000 = 9.47$, which requires a 7-in 15-lb beam (Table IV, page 355).

If the beam were not continuous an 8-in 18-lb beam would be required for the 12-ft spans, and a 7-in 15-lb beam for the 10-ft span.

For a beam of two equal spans, loaded uniformly, the strength is the same as though it were not continuous.

The formulas given for the reactions at the supports, and for the deflections of continuous girders with concentrated loads, were verified by Mr. Kidder by means of careful experiments on small steel bars. The remaining formulas were verified by comparing them with the formulas of other authorities where it was possible to do so. In regard to some of the cases given the author has never seen any discussion of them in any work on the subject.

7. Continuous Girders in Grillage-Foundations

Grillage-Beams Considered as Inverted Continuous Girders. As stated in the beginning of this chapter, CONTINUOUS GIRDERS, as such, are seldom used in building-construction, although their employment in grillage-beam footings is fre-

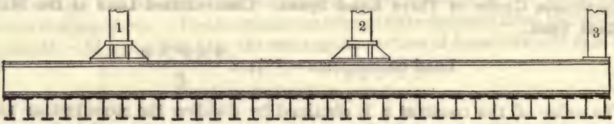

Fig. 3. Continuous Girder in Grillage-foundation

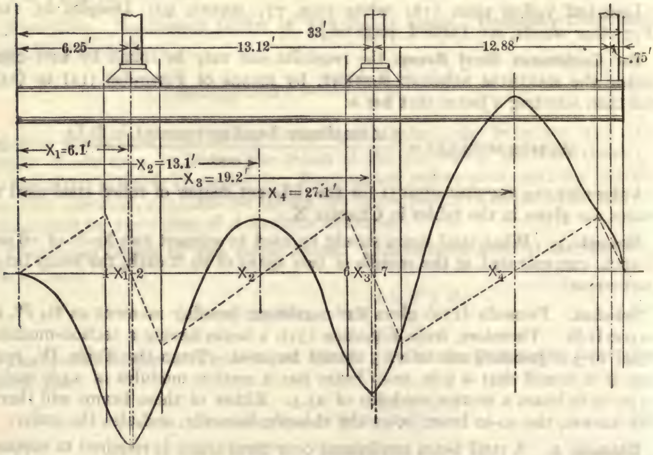

Fig. 4. Shear-diagram and Bending-moment Diagram

quent. Fig. 3 represents a footing consisting of two layers of beams, which distribute the load of the three columns above, uniformly over the foundation-bed. By inverting the footing the three columns become the supports or reactions, and the upper layer of beams, a continuous girder, loaded with a uniformly distributed load which is the pressure of the lower layer. As in practice the column-

loads are never equal, and the distance between the columns seldom equal, it is necessary to project the continuous girder beyond the most heavily loaded column in order to insure a uniform pressure upon the lower layer. Because of these limitations none of the formulas previously deduced can be applied, although the principles upon which they are based hold good.

Maximum Bending Moment. Since the REACTIONS in this case are the given column-loads it is required first to find the MAXIMUM BENDING MOMENT. From what has already been said about continuous girders, it is evident that the point of maximum bending moment may be under columns 1 or 2, or between the columns. Since the maximum bending moments are the POINTS OF NO SHEAR, construct the SHEAR-DIAGRAM, find where the shear passes through zero, and calculate the bending moments at these points. The maximum bending moment is determined, as in examples 1 and 2, in order to determine the SECTION-MODULUS of the girder.

Example 3. The continuous girder under columns 1, 2 and 3 (Fig. 3) is 33 ft long; the overhang, to the left of column 1, 6.25 ft; the distance between columns 1 and 2, 13.12 ft; between columns 2 and 3, 12.88 ft; and from column 3 to the right edge of the girder, .75 ft. The column-loads are as follows: on column 1, 565 tons; on column 2, 600 tons; and on column 3, 255 tons.

The column-loads may be considered uniformly distributed over parts of the girder by the bases, which are 3 ft wide under columns 1 and 2 and 18 in wide under column 3. The UNIT PRESSURE under column 1, therefore, is $565/3 = 188.3$ tons; under column 2, $600/3 = 200$ tons; and under column 3, $255/1.5 = 170$ tons. The unit pressure under the continuous girder is

$$(565 + 600 + 255)/33 = 43 \text{ tons}$$

The first step in the calculation of the girder is the determination of the POINTS OF NO SHEAR and the plotting of the SHEAR-DIAGRAM in Fig. 4. It is obvious from the shear-diagram that there are four points of no shear and consequently four points of POSSIBLE MAXIMUM BENDING MOMENT. The first of these is under column 1, the second between columns 1 and 2, the third under column 3 and the fourth between columns 2 and 3. The bending-moment diagram is shown by the solid curved line in Fig. 4. The points of contra-flexure or no bending moment are the intersections of this line with the horizontal line of reference.

The SHEAR-DIAGRAM,* shown by the broken line in Fig. 4, may be constructed as follows:

$$V_1\dagger = +43 \text{ tons per ft} \times (6.25 - 1.5 = 4.75 \text{ ft}) = +204.25 \text{ tons}$$

$$V_2 = (+43 \text{ tons per ft} \times 6.25 \text{ ft}) - 565/2 \text{ tons} = +268.75 - 282.5$$
$$= -13.75 \text{ tons}$$

This shows that x_1, the point of no shear, lies between points 1 and 2. To find this point let y be its distance beyond or to the right of point 1. Then, the EQUATION FOR NO SHEAR is 43 tons $\times$ (4.75 ft + y ft) = $188.3 \times y$, or $204.25 + 43\,y = 188.3\,y$, from which $145.3\,y = 204.25$ and $y = 1.4$ ft: hence x_1, the FIRST POINT OF NO SHEAR, is 4.75 ft + 1.4 ft, or 6.1 ft from the left end.‡

The SECOND POINT OF NO SHEAR, x_2, is such a distance from the left end that the DOWNWARD SHEARING-FORCE of 565 tons from column 1 is neutralized by

* The upward forces are here called plus or positive and the downward forces minus or negative.

† V_1 is taken at point 1, the left edge of base of Column 1, V_2 at point 2, at the axis of Column 2, etc.

‡ The following computations are carried out to one decimal-place, only, the nearest approximate values being used.

an equal UPWARD SHEARING-FORCE of 43 tons per ft. on x_2 ft. Hence $x_2 = 565/43 = 13.1$ ft.

$$V_6 = +43 \text{ tons per ft} \times [(6.25 + 13.12 - 1.5) = 17.9 \text{ ft}] - 565 \text{ tons}$$
$$= 769.7 - 565 = +204.7 \text{ tons}$$

$$V_7 = +43 \text{ tons per ft} \times (6.25 + 13.12 = 19.4 \text{ ft}) - (565 + 600/2 \text{ tons})$$
$$= +834.2 - 865 \text{ tons} = -30.8 \text{ tons}$$

This shows that the THIRD POINT OF NO SHEAR, x_3, lies between 6 and 7. Let y be its distance to the right of point 6. The equation for no shear at this point is 43 tons $\times$ (17.9 ft + y ft) = 565 tons + (200 tons $\times$ y ft), or $769.7 + 43y = 565 + 200y$, from which $157y = 204.7$ and $y = 1.3$ ft. Hence x_3, the THIRD POINT OF NO SHEAR, is 17.9 ft + 1.3 ft = 19.2 ft from the left end.

The FOURTH POINT OF NO SHEAR, x_4, is such distance from the left end that the DOWNWARD SHEARING-FORCE of columns 1 and 2, amounting to 565 + 600 or 1165 tons, is neutralized by an equal UPWARD SHEARING-FORCE of 43 tons per ft on x_4 ft. Hence $x_4 = 1\,165/43 = 27.1$ ft.

Having found the points of no shear, the BENDING MOMENT at these points may now be determined.

$$M \text{ at } x_1 = 43 \text{ tons} \times 6.1 \text{ ft} \times 6.1/2 \text{ ft} - 188.3 \text{ tons} \times 1.4 \text{ ft} \times 1.4/2 \text{ ft}$$
$$= +615.5 \text{ ft-tons}$$

$$M \text{ at } x_2 = 43 \text{ tons} \times 13.1 \text{ ft} \times 13.1/2 \text{ ft} - 565 \text{ tons} \times 6.8 \text{ ft} = -152.4 \text{ ft-tons}$$

$$M \text{ at } x_3 = 43 \text{ tons} \times 19.2 \text{ ft} \times 19.2/2 \text{ ft} - 565 \text{ tons} \times 12.9 \text{ ft} - 200\,T \times 1.3 \text{ ft}$$
$$\times 1.3/2 = +467 \text{ ft-tons}$$

$$M \text{ at } x_4 = 43 \text{ tons} \times 27.1 \text{ ft} \times 27.1/2 \text{ ft} - 565 \text{ tons} \times 20.8 \text{ ft} - 600 \text{ tons}$$
$$\times 7.7 \text{ ft} = -582.2 \text{ ft-tons}$$

The MAXIMUM BENDING MOMENT therefore is at x_1 and equals 615.5 ft-tons* or 1 231 000 ft-lb. Substituting in Formula (31), the SECTION-MODULUS is found to be $\frac{3 \times 1\,231\,000}{4\,000} = 923.2$. The following beams could be used, as far as flexure is concerned. For investigations of the resistance of the girders to web-buckling or crippling, see Chapter II, pages 182 to 184, and Chapter XV, pages 567 to 569.

Four standard 24-in 110-lb **I** beams, section-modulus of each, 240.3 (page 354)

Three Bethlehem 30-in 120-lb **I** beams, section-modulus of each, 349.3 (page 357)

Three Bethlehem 24-in 140-lb girder-beams, section-modulus of each, 350.1 (page 358)

Two Bethlehem 28-in 180-lb girder-beams, section-modulus of each, 518.9 (page 358)

The 28-in and 30-in beams are stiffer than the 24-in beams, have a smaller total amount of steel and cost less than the others for the number of beams required.

* The bending moments at x_1 and x_4 have very nearly the same numerical values, and in the computations the retaining or dropping of figures in the second decimal-place may change the result and make the value at x_4 slightly greater than at x_1.

CHAPTER XX

RIVETED STEEL PLATE AND BOX GIRDERS

By

CHARLES P. WARREN

ASSISTANT PROFESSOR OF ARCHITECTURE, COLUMBIA UNIVERSITY

1. General Notes on Plate and Box Girders

Types of Riveted Girders. Girders built up of plates and angles, as shown in section in Figs. 1 to 4, are extensively used. This is undoubtedly owing to the simplicity of their construction, to the comparatively low cost of the shapes of which they are fabricated and to their adaptability to any arrangement of loads or to any span for which girders are usually required. Riveted girders, however, are seldom made for spans greater than 60 ft and are seldom more than 6 ft in depth. The most common forms of these girders are shown in Figs. 2 and 4.

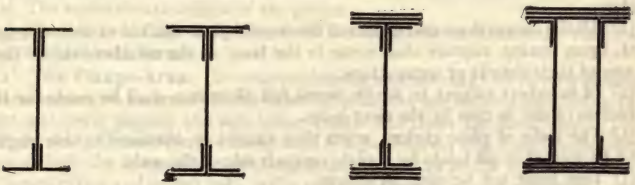

Fig. 1 Fig. 2 Fig. 3 Fig. 4

Types of Riveted Girders

The girders with a single vertical plate called the WEB are usually called PLATE GIRDERS, and those with double or triple webs, BOX GIRDERS. Plate girders are more economical than box girders, and more accessible for painting and inspection; but box girders are stiffer laterally and should always be used where great length of span requires wide flanges. In general, it may be said that plate girders should be used to support floor-beams and floor-arches and walls not over 12 in thick, and that box girders should be used where a flange-width greater than 12 in is required. The girder shown in section in Fig. 1 has no flange-plates and should be used only for comparatively light loads and short spans, and never to support masonry.

Flange and Web. The term FLANGE, as applied to riveted girders, includes all the metal in the top or bottom parts of the girder, exclusive of the web-plates.* The DEPTH of a riveted girder is the distance between the centers of gravity of the flanges; but in practice this is usually taken as the DEPTH OF THE WEB-PLATE, and the word will be so used in this chapter. The top and bottom of the flange-angles extend ¼ in beyond the top and bottom of the web-plate. (See the figure in Table IV, page 706.) STIFFENERS are short pieces of angles

* This may be modified, however, as some engineers include one-sixth of the web-area in the effective flange-area. See, also, Flange-Area in the examples of this chapter.

riveted to the web at intervals, to keep it from BUCKLING. They should fit closely against the horizontal flanges of the flange-angles, and should always be used at the supports and under concentrated loads.

Economic Depths of Girders. The depth of a riveted girder may vary from one-tenth to one-fifteenth or, in exceptional cases, one-sixteenth the span. The greatest economy of material is said to be obtained when the depth is one-twelfth the span. Thus for a 36-ft span a 3-ft girder should be used if the conditions will permit; but the least depth should be 1/15 of 36, or about 2 ft 5 in or, in exceptional cases, 1/16 of 36, or 2 ft 3 in. A girder is said to have its ECONOMIC DEPTH when the amount of material in the flanges is equal to that in the web, and there are no cover-plates. The rule holds approximately when there are cover-plates.

The Width of the Top Flange should not be less than one-twentieth the distance between lateral supports; or if there are no lateral supports, then not less than one-twentieth the span.

Arches Between Girders, or floor-beams riveted to the sides of girders, may be considered as LATERAL SUPPORTS.

2. Details of Construction of Plate and Box Girders*

General Requirements for Plate and Box Girders. The following requirements are those which must be generally satisfied in the design of riveted girders.

(1) All the connections and details of the several parts shall be of such strength that, upon testing, rupture shall occur in the body of the members rather than in any of their details or connections.

(2) In members subject to tensile stress full allowance shall be made for the reduction of the section by the rivet-holes.

(3) The webs of plate girders, when they cannot be obtained in one length, must be spliced at all joints by a plate on each side of the web.

(4) Tees must not be used for splices.

(5) Stiffeners shall be used at the ends of all girders, wherever there are concentrated loads, and elsewhere when the shearing-stress is greater than the resistance to buckling.

(6) The PITCH, that is, the distance between centers of rivets, shall not exceed 6 in, nor 16 times the thickness of the thinnest outside plate, and it shall not be less than 2¼ in for ¾-in rivets, or 2⅝ in for ⅞-in rivets, in a straight line.

(7) The rivets used should be ¾ in in diameter for plates from ⅜ to ⅝-in thick, and ⅞ in in diameter for plates of greater thickness.

(8) The distance between the edge of any piece and the center of a rivet-hole must never be less than 1¼ in.

(9) In PUNCHING plates or other members, the diameter of the die shall in no case exceed the diameter of the punch by more than 1/16 in.

(10) All RIVET-HOLES must be so accurately punched that when the several parts forming one member are assembled, a rivet, 1/16 in less in diameter than the hole, can be inserted, hot, into any hole without REAMING or stressing the metal by the use of drift-pins.

(11) The rivets when driven must completely fill the holes.

(12) The RIVET-HEADS must be hemispherical. except where flush surfaces are required, and of uniform size throughout for rivets of the same size. They must be full and neatly made, and be concentric with the rivet-holes.

* These requirements are taken largely from Birkmire's "Compound Riveted Girders."

(13) Whenever possible, all rivets must be MACHINE-DRIVEN.

(14) The several pieces forming one built member must fit closely together, and, when riveted, must be free from twists, bends or open joints.

(15) Girders 60 ft and less in length seldom require SPLICING, as the plates and angles can readily be obtained in such lengths. In splicing the top flange, when of two or more thicknesses, no additional COVER-PLATE will be required over the joint, but the ends should be planed true and butt closely. The rivets should be spaced closer near the joint.

(16) The plate covering the bottom flange must be of the same area as the plates joined, and of sufficient length to take a number of rivets equal to the strength of the cover-plate.

3. Design of Plate and Box Girders

The Principal Steps in the Design of Riveted Girders. In designing a riveted girder to sustain with safety a given load, the following steps are necessary:

(1) The determination of the required flange-area.

(2) The determination of the thickness of the web to resist

 (*a*) Shearing,

 (*b*) Buckling. This step also determines whether or not stiffeners are necessary.

(3) The determination of the number and pitch of the rivets.

(4) The approximate weight of the girder.

(5) The determination of the length of the flange-plates when more than one is required for each flange.

(1) The Flange-Area. In determining the FLANGE-AREA of riveted girders, it is customary to assume that the bending moments are entirely resisted by the upper and lower flanges, the web being assumed to resist the shear only. Just what should be included in the flange-area is a question on which engineers differ. Some include the flange-plates and angles and one-sixth of the web-area, others the flange-plates and angles only, while others include the flange-plates and only the horizontal legs of the angles, the vertical legs being considered as belonging to the web. In compression-flanges, usually the upper ones, the gross section-area may be taken, provided the rivets are machine-driven and fill completely the holes; but in tension-flanges, usually the lower ones, the net area is taken, that is, the gross area minus the area of the greatest number of rivet-holes in any cross-section, since the stresses of tension are not transmitted through the rivets as are those of compression.

A general FORMULA* FOR DETERMINING THE FLANGE-AREA, which applies to all conditions of loading is

$$\text{Area of one flange in square inches} = \frac{\text{maximum bending moment in foot-tons}}{\text{depth of web in feet} \times \text{safe unit fiber-stress in tons}}$$

or

$$A = M_{\max}/dS \tag{1}$$

* This may be derived from what is sometimes called the PLATE-GIRDER FORMULA, $M_{\max} = SAd$, in which S is the safe unit bending-stress in the flange at the section of maximum bending moment, A is the area of the cross-section of either flange and d is approximately the depth of the girder. Of course the units must be the same in both members of the equation. If the center of moments is taken at the center of gravity of the cross-section of either flange-area and if the area of metal resisting bending is considered to be concentrated in the flanges, the depth of each being very small compared to that of the girder-depth, then SA is the total horizontal stress in either flange, d its lever-arm and SAd the resisting moment of the cross-section, equal to $M_{\max}$. Hence $A = M_{\max}/dS$.

Rules for finding the MAXIMUM BENDING MOMENT for different conditions of loading are given in Chapter IX.

S, the SAFE UNIT FIBER-STRESS FOR FLANGE-BENDING, is taken at from 13 000 to 16 000 lb per sq in, the tables in the manufacturers' handbooks giving the safe loads, etc., for riveted girders, varying in regard to this stress.*

If it is required to compute the SAFE UNIFORMLY DISTRIBUTED LOAD for a girder already constructed or designed, the following formula † may be used. The safe load in pounds, uniformly distributed is

$$W = \frac{8 \times \text{net area of bottom flange} \times \text{depth in ft} \times S}{\text{span in feet}}$$

or

$$W = 8AdS/l \qquad (2)$$

From the result the weight of the girder itself should be subtracted.

For the SAFE CONCENTRATED LOAD AT THE MIDDLE OF THE SPAN take one-half the result obtained by formula (2) and subtract the weight of girder. (See Case IV, page 326.)

(2) The Thickness of the Web. The thickness of the web is determined by its resistance to VERTICAL SHEARING. Whether or not stiffeners shall be used is determined by the resistance of the web to BUCKLING.

(a) Shearing. To resist the vertical shear the NET SECTIONAL AREA OF THE WEB in square inches must be

$$A = \frac{\text{the maximum vertical shear}}{S}$$

or

$$A = V_{\max}/S \qquad (3)$$

V and S being both in tons, S is taken at 10 000 ‡ lb or 5 tons per sq in. (See Table II, page 703.)

The MAXIMUM VERTICAL SHEAR in any beam or girder is at the greater reaction and is equal to it.

For a girder supported at both ends and uniformly loaded with a load W, the MAXIMUM VERTICAL SHEAR is

$$V_{\max} = W/2$$

For a girder supported at both ends and loaded at the middle with a load P,

$$V_{\max} = P/2$$

For a girder supported at both ends and loaded as in Fig. 7,

$$V_{\max} = Pm/l = R_1$$

For a girder supported at both ends and loaded with two equal concentrated loads P, P, equally distant from the middle, as in Fig. 8,

$$V_{\max} = P = R_1 = R_2$$

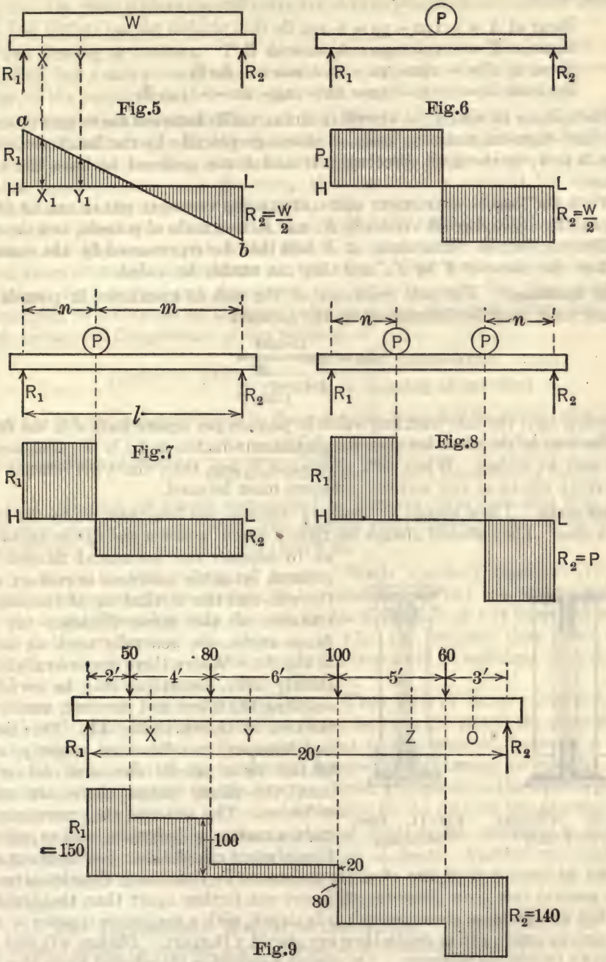
For combinations of loads the maximum vertical shear will equal the greater reaction. The method of determining the REACTIONS at the supports of a beam or girder is given in Chapter IX, Subdivision 1. The VERTICAL SHEARING-

* See Chapter XV, paragraphs relating to riveted single and double-beam girders and foot-note with same, pages 603 and 604.

† From Formula (1) just explained, and from Case V, page 326, $M_{\max} = SAd$ and $M_{\max} = Wl/8$. Hence $Wl/8 = SAd$ and $W = 8\,AdS/l$.

‡ This is a conservative value. The Carnegie Pocket Companion and the building laws of most cities permit 10 000 lb per sq in for steel.

FORCE at any given vertical section of a beam or girder between the supports is the algebraic sum of all the vertical external forces acting on the beam to the



Figs. 5 to 9. Diagrams for Vertical Shears for Different Loadings

left of that section, forces acting upwards being considered as plus, and those acting downwards being considered as minus.

Thus, in the case of the beam shown in Fig. 9, the REACTION R_1 will be found, by the method explained in Example 2, page 323, and by Formulas (2).

and (3), page 323, to be 150 lb, and that at R_2 to be 140 lb. The shear at various sections may be found by applying the foregoing definition of VERTICAL SHEAR, thus:

Shear at $X = +150 - 50 = +100$ lb
Shear at $Y = +150 - 50 - 80 = +20$ lb
Shear at $Z = +150 - 50 - 80 - 100 = -80$ lb
Shear at $O = +150 - 50 - 80 - 100 - 60 = -140$ lb

The manner in which the VERTICAL SHEAR varies between the supports, under different dispositions of the loads, is shown graphically by the hatched areas in Figs. 5 to 9; in the first three cases W and P are assumed to have the same value.

When the load is UNIFORMLY DISTRIBUTED the VERTICAL SHEAR can be found graphically by laying off vertically R_1 and R_2 to a scale of pounds, and drawing the line ab, Fig. 5. The shear at X will then be represented by the ordinate X_1 and the shear at Y by Y_1, and they can readily be scaled.

(b) Buckling.* The safe resistance of the web to BUCKLING, in pounds per square inch, may be determined by the formula

$$S_b = \frac{10\,000}{1 + \dfrac{d^2}{3\,000\,t^2}} \tag{4}$$

in which S_b is the safe buckling value in pounds per square inch, d is the depth of the web in the clear between flange-plates in inches and t is the thickness of the web in inches. When this resistance is less than the UNIT STRESS FOR VERTICAL SHEAR at any section, stiffeners must be used.

Stiffeners. These should be made of ANGLES, not less than 3½ by 3½ by ⅜ in in size. They should always be tightly fitted between the flange-angles, so as to support the horizontal flanges. In order to bring the stiffeners in contact with the web and the vertical leg of the angles, FILLERS, of the same thickness as the flange-angles, are generally used, as shown in Fig. 10. Where there are several girders exactly alike, something may be saved by omitting the fillers and BENDING THE STIFFENERS, as shown in Fig. 11. This bending, however, can be done properly, only by the use of special dies, and costs more than the fillers unless there are many stiffeners. The SPACING OF STIFFENERS is more a matter of judgment and experience than of exact calculation. SHEAR-DIAGRAMS, shown in Figs. 5 to 9, are of great assistance in visualizing shearing-stresses. The general rule is to place the stiffeners not farther apart than the depth of the full web-plate on girders over 3 ft in depth, with a maximum spacing of 5 ft. On girders under 3 ft in depth they are placed 3 ft apart. Girders 2 ft and less in depth require no stiffeners. On girders supporting distributed loads they are generally placed nearer together at the ends than towards the middle.

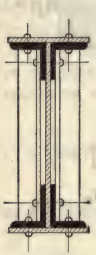


Fig. 10. Stiffeners with Fillers

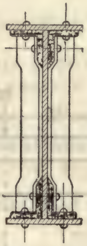

Fig. 11. Bent Stiffeners

* See Table III, page 705, and also in Chapter XV, the paragraphs and foot-note, pages 567 to 569, relating to the web-buckling of beams and girders. The formula used for web-buckling in Table III, page 705, is the formula that was used in the Passaic Steel Company's Manual, and as the values computed by it vary but little from those deduced by the Cambria formula (see page 568), Table III is retained as it is.

Stiffeners should always be placed at the ends of girders and directly over the edge of each support, as shown in Fig. 18, and wherever there are concentrated loads. On plate girders the stiffeners are always placed on each side of the web; on box girders on the outside only.

The Bearing of Girders. This depends somewhat upon the character of the loading, but a safe general rule is to make the BEARING of the girder beyond the edge of the support equal to ONE-HALF THE DEPTH OF THE GIRDER.

(3) The Number and Pitch of the Rivets. **(a) Rivets in Web-Legs of Angles.** It will readily be seen that when a plate or a box girder is loaded, the tendency of the bending moments is to cause the flange-plates and angles to SLIDE HORIZONTALLY past the web; this tendency is resisted by the rivets which connect the angles with the web. The TOTAL AMOUNT OF THIS TENDENCY TO SLIDE, called the HORIZONTAL FLANGE-STRESS, between any section of the flange and the nearer end of the girder, is equal to the BENDING MOMENT at that point DIVIDED BY THE DEPTH OF THE WEB.* The TOTAL NUMBER OF RIVETS between that section and the nearer end must be such that their combined resistance to SHEARING or BEARING, whichever has the lower value, shall equal this horizontal flange-stress at the section; or

$$\text{number of rivets} = \frac{\text{horizontal flange-stress}}{\text{bearing or shearing of one rivet}} \qquad (5)$$

and the total number of rivets in the web-angle from end to end is twice this, or

$$\text{total number of rivets} = \frac{2 \times \text{maximum bending moment}\dagger \text{ in foot-pounds}}{\text{depth of web in feet} \times \text{least resistance of one rivet}} \qquad (6)$$

If the NUMBER OF RIVETS determined by formula (6) is such that they would be more than 6 in apart, then the number must be increased, as in no case should they have a greater PITCH than 6 in.

(b) Rivets in Flange-Legs of Angles. WITH A SINGLE COVER-PLATE. For girders with a single cover-plate, it is customary to put the same number of rivets in the flange-leg as in the web-leg for a distance of 3 ft from the ends of the girder, STAGGERING the rivets as in Fig. 15. Beyond that point to the middle of the girder one-half the number of rivets will be sufficient, provided this will not give them a greater pitch than 6 in.

WITH TWO OR MORE COVER-PLATES. When two or more cover-plates are used, each plate must have sufficient rivets between the end of the plate and the point where its resistance is required, that is, for example, between *a* and *b*, Fig. 13, to transfer to the angle and flange-plates between, an amount EQUAL TO THE SAFE STRENGTH OF THE PLATE. From this point to the middle point of the girder, the rivets can be spaced according to the rule for the greatest pitch.

(c) Rivets in Stiffeners. The spacing of rivets in the stiffeners is generally determined by the rules given for the pitch of rivets. Further explanation of the method of determining the spacing of rivets will be found in the following examples.

(4) The Approximate Weight of the Girder. In determining the size of a riveted girder to support a given load, it is desirable to be able to add to the

* See Formula (1), page 683, and foot-note relating to it. $M = SAd$, and hence $SA = M/d$, SA being the total amount, in pounds, of the tendency to slide, and S being the horizontal unit, flange, fiber-stress in pounds per square in, due to flexure. A is the area in square inches of the cross-section of the flange and d is the approximate depth of the girder.

† Because the maximum horizontal flange-stress is equal to the maximum bending moment divided by the girder-depth, or $S_{max}A = M_{max}/d$.

superimposed load the WEIGHT OF THE GIRDER itself, as this often forms a considerable part of the load to be supported. The following empirical rule* is often used to determine the approximate weight of a plate or box girder:

$$\text{Weight of girder between supports, in tons} = Wl/700 \qquad (7)$$

in which W equals the load to be supported, in tons, and l equals the span, in feet. The constant 700 was determined for girders of from 35 to 50 ft long, but may be used without much excess for girders of shorter spans.

(5) **The Determination of the Lengths of the Flange-Plates.** For the methods used to determine these, see the following examples.

4. Explanation of Tables

The Calculations for the Design of Riveted Girders may be greatly facilitated by the use of Tables I, II, III and IV at the end of this chapter.

Table I gives the sectional area that should be deducted for rivet-holes in plates of different thicknesses. In computing this table ⅛ in was added to the diameter of the rivet to allow for the injury to the metal caused by punching and also to allow for the expansion of the heated rivet.

Table II gives the safe shearing value for web-plates for various depths and thicknesses, and the deduction to be made for each ¾-in or ⅞-in rivet.

Table III gives the safe resistance to buckling per square inch of net section, and also the total safe resistance in pounds for the more common sizes of web-plates, with two rivet-holes deducted. It is very seldom that any vertical section between the stiffeners contains more than two rivet-holes. Tables giving the dimensions and properties of angles will be found in Tables XI and XII, pages 362 to 367, and the shearing value and bearing values of rivets are given in Tables II and III, pages 418 and 419.

Table IV gives the elements of riveted plate girders of various depths, from which it is possible to select economical sections for almost any ordinary condition of loading.

5. Examples of Plate and Box Girders

Example 1. It is required to support the floor over a room 50 by 64 ft, by means of riveted steel plate girders, placed across the room, 16 ft on centers. The room above is to be used for general assembly purposes. The floor-joists are of wood and there is a plaster ceiling on the under side of them. The design of the girder is required.

First Step. The Load. The first step is to determine the load to be supported by each girder. The floor-area supported by each girder is 50 by 16 ft, or 800 sq ft. The weight of the floor-construction between the girders will not be over 25 lb per sq ft, and an allowance of 100 lb per sq ft for the live load will be ample. The unit load, 125 lb × 800 = 100 000 lb, or 50 tons, the load to be carried by the girder. To this should be added the weight of the girder itself. Substituting in Formula (7),

$$\text{the approximate weight of the girder} = \frac{50 \times 50}{700} = 3.57 \text{ tons, or about } 7\,000 \text{ lb},$$

and the total load, in round numbers, is 107 000 lb. This, of course, is uniformly distributed.

* From "Compound Riveted Girders," by W. H. Birkmire.

Second Step. The Flange-Area. The next step is to determine the flange-area. Before this can be done, however, the width and depth of the girder must be decided. As it is desirable to keep the girder as shallow as possible, consistent with good engineering, the case will be considered an exceptional one and the depth of the web-plate will be made 36 in, which is about one-sixteenth the span and a little less than the usual limit.

As the girders are braced sidewise by the floor-joists, it will not be necessary to make the width of the flange-plates one-twentieth the span of the girder, and it may be made 12 in width. The flange-area may be determined by Formula (1), page 683, and is

$$A = M_{\max}/dS$$

or

$$\text{flange-area (sq in)} = \frac{\text{maximum bending moment (ft-tons)}}{\text{depth of web (ft)} \times S \text{ (tons per sq in)}}$$

The maximum bending moment for a uniformly distributed load on a simple beam is $M_{\max} = Wl/8$ (Case V, page 326), or in this particular case, 53.57 tons $\times$ 50 ft/8 = 334.8 ft-tons.

The value of S * has varied in the handbooks from 6 to 8 tons, depending upon varying conditions and upon the judgment of engineers. A value of S of 7 tons or 14 000 lb per sq in is the requirement of the new New York Building Code.

Substituting these values in the formula gives for the net area of either flange, $334.8/3 \times 7 = 16$ sq in.

The upper flange may now be designed. For a girder of this size and loaded in this way, it will be advisable to try two 5 by 3½ by 7/16-in angles, with the long legs horizontal.† The sectional area of these angles (Table XI, page 363) is 7.06 sq in which leaves 9 sq in for the area of the flange-plates. Dividing this by 12-in, the width of the flange, gives ¾ in for the total thickness of the plates, which may be made up of two ⅜-in thick plates. Of course, any other combination of plates and angles having an area of cross-section of 16 sq in will fulfill the conditions of the problem, the selection in all cases depending upon the judgment and experience of the designer. Note, also, that no part of the web has been included in the flange-area although it would be safe to include one-sixth of it. This also is a matter of individual opinion.

As the lower flange is in tension, the rivet-holes should be deducted in order to obtain the net area. Assuming that ¾-in diameter rivets are used, it will be noted that the greatest loss of section is by two rivet-holes opposite each other, connecting the angles with the plates of the bottom flange. From Table I, page 702, the area of two ¾-in rivets in a ¾-in plate is 1.31 sq in, and in a 7/16-in plate, the same thickness as that of the angles, it is 0.76 sq in. The sum of these thicknesses is 2.07 sq in, which must be added to the net area of the upper flange-plates, 16 sq in, making 18.07 sq in for the gross area of the lower

* See, in Chapter XV, paragraphs and foot-notes, page 603, relating to fiber-stresses for bending for riveted beam girders, etc.

† For the flange-angles of plate girders the 5 by 3½-in size is most commonly used, when the flange-plate is 12 in wide, and 6 by 4-in angles when the flange-plate is over 12 in wide. For box girders 5 by 4, 5 by 3½, 4 by 3½ and 3½ by 3½-in are common sizes; while for very heavily loaded girders, requiring two rows of rivets in the web-leg, 6 by 6-in angles are often used. For most riveted girders, in which only one row of rivets is required, the short leg is riveted to the web, so as to bring most of the material as far from the neutral axis of the girder as possible. The minimum thickness of flange-angles should be ⅜ in, and the maximum thickness for ordinary loads is ¾ in.

flange-plates. This additional area may be obtained by increasing the thickness of the plates to ½ in.

The flanges will then be made up as follows:

Upper flange:	Two angles 5 by 3½ by 7/16-in	= 7.06 sq in, gross area
	Two plates 12 by 3/8-in	= 9.00 sq in, gross area
	Total	16.06 sq in. gross area
Lower flange:	Two angles, 5 by 3½ by 7/16-in	= 7.06 sq in, gross area
	Two plates, 12 by ½-in	= 12.00 sq in, gross area
	Total	= 19.06 sq in, gross area

Third Step. The Length of the Flange-Plates. To determine this it is necessary to plot the bending-moment diagram shown in Fig. 12. The bending-

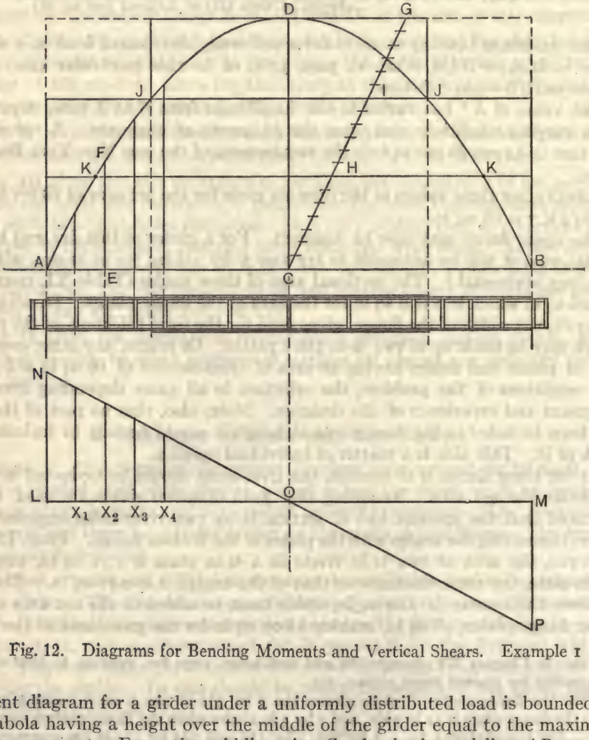

Fig. 12. Diagrams for Bending Moments and Vertical Shears. Example 1

moment diagram for a girder under a uniformly distributed load is bounded by a parabola having a height over the middle of the girder equal to the maximum bending moment. From the middle point *C*, of a horizontal line *AB*, at any convenient scale, lay off a vertical line *CD*, equal to the maximum bending moment, 334.8 ft-tons. Construct the parabola *ADB* (see page 79); then the bending moment at any other point, as *E*, is equal to the ordinate *EF* above that point, measured to the same scale.

To find the theoretical length of the flange-plates of the lower flange, inclose the bending-moment diagram in a rectangle and from any convenient point, such as C, lay off any line CG, equal to the total flange-area, 19 units in length, and at such an angle that the upper end G will lie on a horizontal line drawn through D. Divide the line CG into three parts, CH representing the sectional area of the angles, equal to 7 units, and HI and IG representing the sectional area of the two plates, equal to 6 units each. Draw horizontal lines through H and I; then the line JJ will represent the theoretical required length of the second or upper flange-plate and the line KK the length of the first or lower flange-plate. In practice, however, the plates are usually extended beyond the points J and K on each side as an additional factor of safety, a distance sufficient to take enough rivets to transmit at least one-third the resistance of the plate. It is also customary to make the first or lower flange-plate the full length of the girder as it greatly stiffens the angles and adds but a small amount to the cost. Theoretically the length of the flange-plates of the top flange would be less than the length of the plates of the lower flange, because the flange-area of the top flange is less than that of the lower flange; but they are usually made the same length.

Fourth Step. The Web. Webs are proportioned to resist the shear. The maximum shearing-stress in a girder uniformly loaded is equal to either reaction, which in this case is one-half the total load, or 53 500 lb. As the girder is 3 ft deep, this small shear would require a very thin section, thinner than the minimum thickness for webs, which is ⅜ in. From Table II, page 703, it is seen that the shearing resistance of a ⅜ by 36-in web-plate is 135 000 lb, which is greatly in excess of the actual shear.

Fifth Step. The Stiffeners. As before explained, stiffeners will be required whenever the vertical shear exceeds the safe resistance of the web to buckling. The vertical shear is 53 500 lb and the resistance to buckling may be found from Table III, page 705. This, for a ⅜ by 36-in web with two ¾-in rivets is found to be 31 560 lb; hence stiffeners will have to be used. As stated under Buckling of Web, page 686, the spacing of stiffeners is more a matter of judgment and experience than of exact calculation, and for this a shear-diagram, also shown in Fig. 12, is of great assistance. It may be constructed as follows: On a horizontal line LM, lay off to any convenient scale vertical lines LN and MP, each representing 53 500 lb. Connect the points N and P; then the vertical shear at any point is equal to the ordinate at that point, measured to the same scale. Thus, at X_1, 3 ft from the left end, the shear is 47 500 lb, at X_2, 6 ft from L, it is 40 500 lb, at X_3, 9 ft from L, it is 34 000 lb and at X_4, 12 ft from L, it is 27 500 lb. As the vertical shear at X_3 is greater than the safe resistance to buckling and at X_4 less, it might be safe to stop the stiffeners at X_4; but as the floor-joists are framed flush, or nearly so, with the top of the girder, and rest upon angles riveted to its web, it will be advisable to put about 3 stiffeners between X_4 and the corresponding point on the right-hand half of the girder. Additional stiffeners should be placed directly over each support, making 15 stiffeners on each side of the girder. These will be made of 4 by 4 by ⅜-in angles.

Sixth Step. The Number and Pitch of the Rivets. First, the number of rivets in the web will be considered. As a rivet is required at the end of each stiffener, it will be necessary to determine the number and spacing of the rivets between each pair of adjacent stiffeners. In the web, the rivets are in double shear. In Tables II and III, pages 418 and 419, values are given based upon unit shearing values of 7 500 and 10 000 and bearing values of 15 000 and 18 000 lb per sq in. (See foot-notes with these tables.) The shearing resistance

of a ¾-in rivet at 10 000* lb per sq in is 4 420 × 2 = 8 840 lb for double shear, and the bearing value of the same rivet in a ⅜-in plate, at 20 000* lb per sq in, is 5 630 lb. As the bearing value is the smaller, it will determine the number of rivets required.

The number of rivets from either end of the girder to any point depends upon the horizontal flange-stress at that point, and it has been shown that the flange-stress is equal to the bending moment divided by the depth of the web. (See foot-notes with Equations (5) and (6).) Scaling off the bending moment above the point X_1 gives 75 ft-tons; hence the horizontal flange-stress is equal to 75/3 = 25 tons = 50 000 lb. The number of rivets required between this point and the left reaction is, from Formula (5), equal to 50 000/5 630 = 10 rivets, which are to be spaced in a distance of 36 in, making the spacing 3.6 in. Above X_2 the bending moment scales 141.24 ft-tons, the flange-stress is 141.24/3 = 47.08 tons, or 94 160 lb, and the number of rivets required between X_2 and A is 94 160/5 630 = 17; but 10 of these are required between X_1 and A, leaving 7 to be placed between X_1 and X_2 in a distance of 36 in making the spacing 5.1 in. At X_3, the bending moment scales 197.4 ft-tons, and the flange-stress is 197.4/3 = 65.3 tons, or 130 600 lb. The number of rivets required is 130 600/5 630 = 24, but 17 of these are required between X_2 and A, leaving 7 to be placed between X_2 and X_3, making the spacing the same as in the second panel. At X_4 the bending moment scales 243.96 ft-tons, and the flange-stress is 243.96/3 = 81.32 tons or 162 640 lb. The number of rivets required is 162 640/5 630 = 30, but 24 of these are required between X_3 and A, leaving 6 to be placed between X_3 and X_4 in a distance of 36 in, making the spacing 6 in. As this is the maximum spacing allowed, it will be used from X_4 to the corresponding point on the opposite right-hand half of the girder. The same number of rivets will be used in the flange-legs of the angles as in the web-legs, but they will be spaced so that they will come between those in the web.

The outer flange-plate scales 28 ft 6 in in length in the bending-moment diagram, but this length, as before stated, should be increased sufficiently to take enough rivets to transmit at least one-third of the resistance. The area of the plate is ½ in × 12 in = 6 sq in, minus the area of two ¾-in rivet-holes, 0.87 sq in (Table I, page 702), leaving a net area of 5.13 sq in. The resistance of the plate is therefore equal to 5.13 sq in × 14 000 lb per sq in = 71 820 lb. One-third of this, or 23 940 lb, must be transferred by rivets placed beyond the points JJ. As the rivets in the flange are in single shear, the shearing value of one rivet in single shear, 4 420 lb, will govern. The number of rivets required, then, is 23 940/4 420 = 6, or 3 in each angle. The spacing of the rivets in this panel is 6 in. The plates will therefore be extended 18 in on either side of JJ.

* The shearing value of rivets is taken at from 7 000 to 12 000 lb per sq in and the bearing value at from 12 000 to 24 000 lb per sq in. The usual values are 10 000 lb for shear and 18 000 or 20 000 lb for bearing. Values of 10 000 lb for shear and 20 000 lb for bearing are the requirements of the New York Building Code. A bearing value other than those of Tables II and III, pages 418 and 419, is purposely used in this example, as it is frequently necessary to use different unit stresses than those from which some particular table has been computed. If no other table is at hand for the values based upon some particular rivet bearing-stress, Tables II and III, pages 418 and 419, can be used and the new value found by proportion; or the bearing-stress can be found by multiplying the product of the diameter of the rivet and the thickness of the web by the new unit stress. In this example, Table III, page 419, gives, for 18 000 unit stress, 5 060 lb for bearing; 10/9 of this gives 5 622 lb for a 20 000 unit stress. Also, ⅜ in by ¾ in by 20 000 lb per sq in = 5 625 lb. The Cambria handbook uses this value, and Carnegie's Pocket Companion, and Merriman's Civil Engineers' Pocket Book use 5 630 lb, which is the value used here.

Splices. As the total length of the girder is but 53 ft, it will not be necessary to splice the webs or the flanges, because the extreme length of a ⅜ by 36-in plate is 110 ft and of a 12 by ½-in plate, 90 ft.* It is never necessary to splice angles as they are rolled in lengths up to 90 ft. In very long, deep girders, however, it is sometimes necessary to splice the web, and the joint is sometimes made at the middle, as theoretically there is no vertical shearing-stress in the web

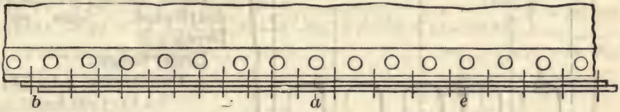

Fig. 13. Splicing of Inner Plate of Bottom Flange of Plate Girder. Example 1

at that point when the load is uniformly distributed. Generally, however, the web is spliced in two places, equidistant from the middle of the girder. The splice is calculated for vertical shear only, the rule being to divide the shear at the splice by the safe shearing value or bearing value of one rivet. This gives the number of rivets required on each side of the splice-plate, unless the maximum pitch is exceeded, when more are added.

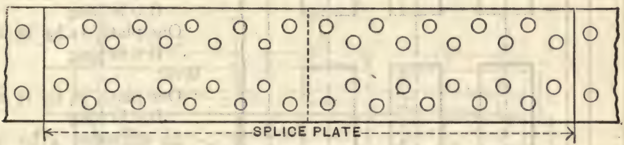

Fig. 14. Plan of Splice-plate. Example 1

Whenever a splice is required in a flange-plate, it should be, if possible, at a point just beyond the end of the plate above it. The joint must be made by riveting to the spliced plate, a plate of the same thickness and of sufficient length to receive a number of rivets on each side of the joint equal to the strength of the plate that is spliced. When the flange is made up of two plates of the same thickness, the simplest method of splicing the inner plate is as shown in Fig. **13**.

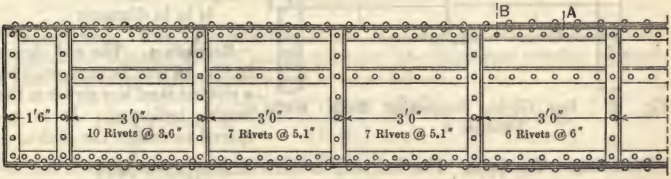

Fig. 15. Elevation of Part of Plate Girder. Example 1

Let *e* denote the theoretical position of the end of the outer plate, as determined by the bending-moment diagram, and *a* the point to which the plate must be extended to receive rivets of a resistance equal to one-third the strength of the plate. Then let the joint in the inner plate be just over *a* and extend the outer plate to *b*, or such a distance that it can receive a number of rivets equal in resistance to the strength of one plate.

* Tables of extreme lengths are published in the various handbooks. The above dimensions, for example, are taken from the table on page 103 of Carnegie's Pocket Companion, 1915 Edition.

Fig. 15 shows one end of the girder, drawn according to the foregoing calculations.

The Bill of Quantities for the Girder. The following is a bill of quantities for the construction of this girder.

Load: 100 000 lb, uniformly distributed. Span 50 ft. Depth 3 ft

Upper flange:
- Two angles, 5 by 3½ by 7/16 in, 53 ft long
- One plate 12 by ⅜ in, 53 ft 0 in long
- One plate, 12 by ⅜ in, 31 ft 6 in long

Lower flange:
- Two angles, 5 by 3½ by 7/16 in, 53 ft long
- One plate, 12 by ½ in, 53 ft 0 in long
- One plate, 12 by ½ in, 31 ft 6 in long

Web:
- One plate, 36 by ⅜ in, 53 ft 0 in long
- 30 stiffeners, 4 by 4 by ⅜-in angles, 2 ft 11 in long
- 30 filler-plates, 4 by ½ in, 29 in long
- 92 ft 8 in of 4 by 4 by ½-in angles for supporting floor-joists

Rivets:
- ¾ in in diameter

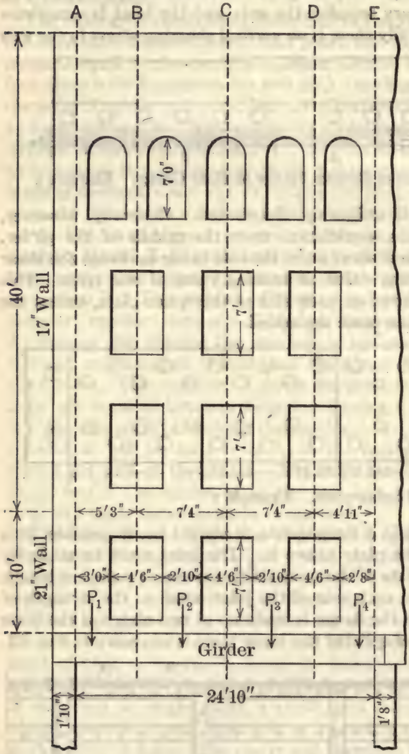

Fig. 16. Box Girder Supporting Brick Wall. Example 2

Example 2. The wall shown in Fig. 16 is to be supported by a riveted-steel box girder at the height indicated. It is required to design the girder.

First Step. The Load. The first step towards designing the girder is the determination of the load. The space under the lower windows is too small to distribute the weight from the piers uniformly over the girder, so that the only safe assumption is that the weight of the wall between the lines A and B is concentrated at P_1, the weight of wall between lines B and C at P_2 and so on. The floor-joists run across the building, so that only the weight of the wall will be supported by the girder. Allowing 200 lb per square foot of face for the 21-in wall, and 165 lb for the 17-in wall, both walls being plastered on the inside:

Load at P_1

$$= \left\{ \begin{array}{l} [5'\,3'' \times 10' - 7' \times 2'\,3''] \times 200 = \ldots\ldots\ldots\ldots\ldots\ldots 7\,350 \\ [5'\,3'' \times 40' - (2'\,3'' \times 14' + 3'\,2'' \times 7')] \times 165 = \ldots\ldots 25\,795 \end{array} \right\} = 33\,145 \text{ lb}$$

Load at P_2

$$= \begin{cases} [7'\,4'' \times 10' - 4'\,6'' \times 7'\,0''] \times 200 = \dots\dots\dots\dots\dots\dots 8\,366 \\ [7'\,4'' \times 40' - (4'\,6'' \times 14' + 4'\,9'' \times 7')] \times 165 = \dots\dots 32\,354 \end{cases} = 40\,720 \text{ lb}$$

Load at P_3 = that at P_2 = ... 40 720 lb

Load at P_4

$$= \begin{cases} [4'\,11'' \times 10' - 2'\,3'' \times 7'] \times 200 = \dots\dots\dots\dots\dots\dots 6\,683 \\ [4'\,11'' \times 40' - (2'\,3'' \times 14' + 3'\,2'' \times 7')] \times 165 = \dots 23\,595 \end{cases} = 30\,278 \text{ lb}$$

Total load on girder = ... 144 863 lb

or 72.4 tons

From Equation (7)

$$\text{approximate weight of girder} = \frac{W \times l}{700} = \frac{72.4 \times 24\tfrac{5}{6}}{700} = 2.5 \text{ tons, or } 5\,000 \text{ lb}$$

About one-third of this, or say 1 600 lb, should be added to P_2 and P_3, and 900 lb to P_1 and P_4. This will give, approximately, the following loads, applied as in Fig. 17:

$P_1 = 34\,000$ lb $\qquad P_2 = 42\,300$ lb

$P_3 = 42\,300$ lb $\qquad P_4 = 31\,200$ lb

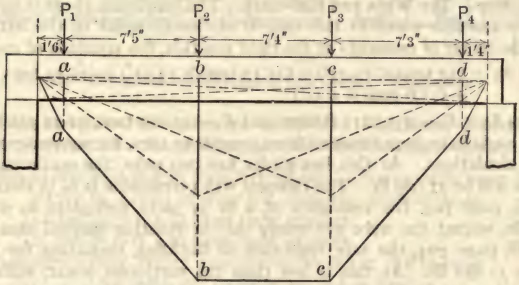

Fig. 17. Diagram for Bending Moments. Example 2

Second Step. The Determination of the Maximum Bending Moment. By means of the formula under Case VI, page 327, the maximum bending moment in foot-pounds for the loads are found to be as follows:

$$\text{For } P_1,\ M_{\max} = \frac{34\,000 \times 1'\,6'' \times 23'\,4''}{24'\,10''} = 47\,980 \text{ ft-lb}$$

$$\text{For } P_2,\ M_{\max} = \frac{42\,300 \times 8'\,11'' \times 15'\,11''}{24'\,10''} = 242\,000 \text{ ft-lb}$$

$$\text{For } P_3,\ M_{\max} = \frac{42\,300 \times 16'\,3'' \times 8'\,7''}{24'\,10''} = 237\,900 \text{ ft-lb}$$

$$\text{For } P_4,\ M_{\max} = \frac{31\,200 \times 1'\,4'' \times 23'\,6''}{24'\,10''} = 39\,420 \text{ ft-lb}$$

Plotting these moments to a scale, as explained for Fig. 15, page 329, the bending-moment diagram shown in Fig. 17 * is obtained. The maximum bend-

* The bending moments in this diagram are drawn to a scale of about 400 000 ft-lb to one inch.

ing moment is at P_2, over the longest ordinate *bb* and where the vertical shear is zero, and is equal to the length of the ordinate *bb*, which scales 418 000 ft-lb, or 209 ft-tons.

Third Step. The Determination of the Flange-Area and the Length of the Cover-Plates. Before these can be determined, the depth of the web-plate must be decided. As there is nothing to limit the depth of the girder, it will be made about one-tenth of the span, or 30 in. Then by Formula (1), page 683, $A = M_{\max}/dS$, and using 14 000 lb or 7 tons per sq in for S,

$$\text{the gross area of upper flange} = 209/2.5 \times 7 = 12 \text{ sq in}$$

As the thickness of the wall to be supported is 21 in, the flange-plate must be at least 20 in wide and not less than ⅜ in thick. The sectional area of a ⅜ by 20-in plate is 7½ sq in, leaving 4½ sq in to be made up by the angles. The sectional area of two 5 by 3½ by 7/16-in angles is 7.06 sq in (Table IX, page 363), which leaves a small excess for the lower flange. For rivets ¾ in in diameter, the loss in area due to two rivet-holes in a ⅜-in plate is (Table I, page 702) 0.65 sq in and in a 7/16-in plate, the thickness of each angle, 0.76 sq in, making 1.41 sq in in all, for which the excess in the angles is more than sufficient. The width of the flange being more than one-twentieth the span makes lateral support unnecessary.

Fourth Step. The Webs and Stiffeners. The maximum shear is equal to the maximum reaction which in this case is obviously equal to the left reaction. Taking the center of moments at the right reaction, the equation of moments is,

$$R_1 \times 24.83' = (17 \text{ tons} \times 23.33') + (21.15 \text{ tons} \times 15.91') + (21.15 \text{ tons} \times 8.58') \\ + (15.6 \text{ tons} \times 1.33')$$

whence $24.83 \times R_1 = 935.3215$ ft-tons and $R_1 = 37.669$ tons, or 75 338 lb. Note that the loads have been changed from pounds to tons, for convenience in making the calculations. As this box girder has two webs, the maximum shear in each web will be 37 669 lb. The thinnest web permissible is ⅜ in thick. From Table II, page 703, the resistance of a ⅜ by 30-in web-plate to shearing is 112 500 lb, so that the webs are amply safe in resisting vertical shear. From Table III, page 705, the safe resistance to buckling, deducting for two ¾-in rivets, is 33 830 lb. As this is less than the maximum shear, stiffeners will be used, placed 2 ft 4 in from each support, with five between them, making the spacing about 3 ft 4 in on centers. Two others will be placed over each support. 4 by 4 by ⅜-in angles will be sufficient for the stiffeners.

Note. If the loads were really concentrated at the points P_1, P_2, etc., as from columns or girders, it would be necessary to place stiffeners at each one of these points and two in each of the intermediate spaces, but as the pier-loads are partly distributed it will be better to space them as first planned.

Fifth Step. The Number and Pitch of the Rivets. The rivets in the web-legs and flange-legs of the angles are in single shear. From Table III, page 419, the shearing value of a ¾-in rivet in single shear at 10 000 lb per sq in is 4 420 lb, and the bearing value in a ⅜-in plate at 18 000 lb per sq in is 5 060 lb. Hence the shearing value will govern. The number of rivets required depends upon the flange-stress, which is equal to the maximum bending moment divided by the depth of the girder. (See Formula (1), page 683.) The bending moment at P_1, found by moments or graphically by scaling off the ordinate *aa*, Fig 17, is 56.5 ft-tons.* This, divided by the depth 2.5 ft, gives 22.6 tons,

* This may be found, also, by taking P_1 as the center of moments and multiplying $R_1 = 37.669$ tons by the lever-arm 1½ ft. The result is 56.5 ft-tons. The bending moments at the other loads may be determined by taking, in each case, the algebraic sum of the moments of the external vertical forces on either side of each point considered.

or 45 200 lb, for the flange-stress, or 22 600 lb for each web. The number of rivets, therefore (Formula (5), page 687) is 22 600/4 420 = 6. The distance from P_1 to the left reaction is 18 in, which makes the spacing 3 in. The flange-stress at P_2 is 209.88 ft-tons/2.5 ft = 83.95 tons, or 167 900 lb, and one-half of this is 83 950 lb. The number of rivets therefore is 83 950/4 420 = 19. But 6 of these are required between P_1 and the left reaction, leaving 13 to go between P_1 and P_2, a distance of 89 in, making the pitch about 6.9 in. As this exceeds the maximum allowable pitch, the rivets will be spaced 6 in on centers between P_1 and P_2, and between P_2 and P_3. The spacing on the right-hand end of the girder will be made the same as that on the left. Some details of the girder are shown in Fig. 18.

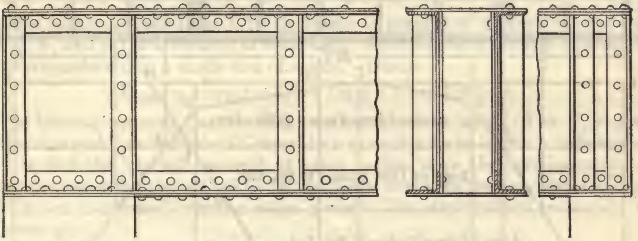

Fig. 18. Elevations and Section of Box Girder. Example 2

The Details and Bill of Quantities for the Girder. The loads, dimensions, size, number of pieces, etc., for the girder are given in the following summary:

Loads: 34 000 lb, 1 ft 6 in from left support. Span: 24 ft 10 in
42 300 lb, 8 ft 11 in from left support. Depth: 30 in
42 300 lb, 8 ft 7 in from right support
31 200 lb, 1 ft 4 in from right support
Both flanges: Four angles, 5 by 3½ by 7/16 in, 27 ft 6 in long
One plate, 20 by 3/8 in, 27 ft 6 in long
Two webs: 3/8 by 30 in, 27 ft 6 in long
Twenty-two stiffeners: 4 by 4 by 3/8 in, 29 1/8 in long
Twenty-two filler-plates: 4 by 7/16 in, 23 in long
Rivets: ¾ in in diameter

Example 3. What are the dimensions of a box girder, 40 ft in span, required to support the following loads? 90 tons from a column, 8 ft from the left support; 75 tons from a column, 12 ft from the right support; and a masonry pier, 10 ft in length, beginning 10 ft from the left support and weighing 4 tons per running ft. (See Fig. 19.)

First Step. The Determination of the Reactions, Shears and Bending Moments. To find either reaction, the center of moments is taken at the other reaction. The equation of moments for the left reaction is, therefore, taking the center of moments at the right reaction,

$$40\,R_1 = (90\text{ tons} \times 32\text{ ft}) + (40\text{ tons} \times 25\text{ ft*}) + (75\text{ tons} \times 12\text{ ft})$$

from which

$$40\,R_1 = 4\,780\text{ ft-tons and } R_1 = 119.5\text{ tons}$$

* In considering the moments of forces, distributed loads are treated as if they were concentrated at their centers of gravity.

In like manner, the equation of moments for the right reaction is

$$40\,R_2 = (75 \text{ tons} \times 28 \text{ ft}) + (40 \text{ tons} \times 15 \text{ ft}) + (90 \text{ tons} \times 8 \text{ ft})$$

from which

$$40\,R_2 = 3\,420 \text{ ft-tons, and } R_2 = 85.5 \text{ tons}$$

The greatest vertical shear V_1 is equal to the greater reaction, which is 119.5 tons. The shear-diagram (Fig. 19) may be constructed by laying off at

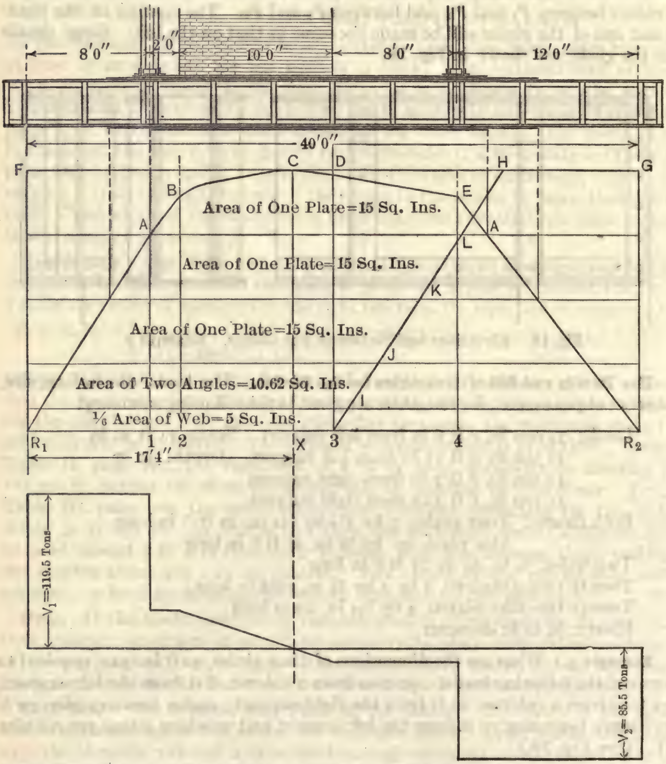

Fig. 19. Elevation of Box Girder and Diagrams for Bending Moments and Vertical Shears. Example 3

any convenient scale an ordinate equal in length to 119.5 tons. Immediately at the right of point 1, under the left column, the shear is equal to $119.5 - 90 = 29.5$ tons. It is the same at point 2, the left end of the wall. At point 3, the right end of the wall, the shear is $119.5 - 90 - 40 = -10.5$ tons, showing that the shear passes through zero somewhere between 2 and 3, which is the point of maximum bending moment. This point, X, is by scaling the shear-diagram, 17.4 ft from R_1. It is over the point of intersection of the slanting line in

the shear-diagram, with the horizontal line of reference. This slanting line is drawn from the top of the shear-ordinate for point 2 to the bottom of the shear-ordinate for point 3. Just at the right of point 4, the shear is $119.5 - 90 - 40 - 75 = -85.5$ tons, the same as the right reaction. The point X, of no shear and maximum bending moment, may be found, also, as follows: At the left of point 2 the shear is 29.5 tons. One foot to the right of 2 it is 29.5 tons $-$ 4 tons $=$ 25.5 tons. Two feet to the right of 2 it is 29.5 $-$ 8 tons $=$ 21.5 tons, etc. Therefore, since the shear decreases at the rate of 4 tons per foot, it will be zero at 29.5/4 or 7.4 ft at the right of 2, or 17.4 ft from R_1.

The maximum bending moment is at X, the point of no shear. The equation of moments, considering the forces to the left of X, is

$$M_{\max} = (119.5 \text{ tons} \times 17.4 \text{ ft}) - (90 \text{ tons} \times 9.4 \text{ ft}) - (4 \text{ tons} \times 7.4 \text{ ft} \times 7.4 \text{ ft}/2)$$

7.4 ft/2 is the distance from X to the center of gravity of the wall-load to the left of X, and is the lever-arm of that load, considered as a vertical downward force concentrated in a single line of action. Hence

$$M_{\max} = 2\,079.3 - 846 - 109.5 = 1\,123.8 \text{ ft-tons}$$

The bending-moment diagram may be constructed by laying off at X, at any convenient scale, an ordinate XC equal to 1 123.8 ft-tons in length. It is necessary to find the bending moment at other points, since the bending-moment diagram cannot be plotted, as in the previous examples, because the uniform load is not distributed over the entire girder. The other critical points are 1, 2, 3 and 4.

$M_1 = (119.5 \text{ tons} \times 8 \text{ ft}) = 956$ ft-tons
$M_2 = (119.5 \text{ tons} \times 10 \text{ ft}) - (90 \text{ tons} \times 2 \text{ ft}) = 1\,015$ ft-tons
$M_3 = (119.5 \text{ tons} \times 20 \text{ ft}) - (90 \text{ tons} \times 12 \text{ ft}) - (40 \text{ tons} \times 5 \text{ ft}) = 1\,110$ ft-tons
$M_4 = (119.5 \text{ tons} \times 28 \text{ ft}) - (90 \text{ tons} \times 20 \text{ ft}) - (40 \text{ tons} \times 13 \text{ ft}) = 1\,026$ ft-tons

By laying off ordinates at these points equal by scale to the respective bending moments; drawing straight lines from R to A, the extremity of the ordinate through 1, and from A to B; drawing curved lines from B through the points C and D; and connecting D and E and E and R_2 by straight lines; the bending-moment diagram $R_1ABCDER_2$ may be constructed.

Second Step. The Webs. As stated on page 683, it is considered safe by many engineers to include one-sixth of the web-area in the flange-area, and this will be done in this example. The web, therefore, must be designed first. As there is nothing to limit the depth of the girder, it will be made 3 ft deep, about one-twelfth the span. The greatest vertical shear is equal to the greater or left reaction, 119.5 tons. Since the girder carries a brick wall, it must be of the box type, and hence the vertical shear on each web is 59.75 tons. A ½ by 36-in web will be tried first. Its area is 18 sq in, from which must be deducted the loss in area due to the rivet-holes for the rivets through the stiffeners. The rivets will be placed the maximum distance on centers, making six in each stiffener. Because of the concentrated loads near the reactions more rivets will be required, and in order to avoid a close spacing, ⅞-in rivets will be used. From Table I, page 702, the sectional area to be deducted for a ⅞-in rivet in a ½-in plate is 0.50 sq in; hence the net area of the web is $18 - (6 \times 0.50) = 15$ sq in, and its shearing resistance, at 10 000 lb or 5 tons per sq in (Table II, page 703), is 15×5 tons $= 75$ tons, which is 15.25 tons in excess of the 59.75 tons required.

Third Step. The Flange-Area. From Formula (1), page 683,

$$\text{the flange area, } A = M_{\max}/dS = \frac{1\,123.8}{3 \times 7} = 53.5 \text{ sq in}$$

As the girder has no lateral support, the flange-width should be not less than one-twentieth the span, which will make it 2 ft.

The upper flange may be proportioned as follows:

One-sixth of net section-area of two webs = ...	5.00 sq in
Two 5 by 5 by 9/16-in angles,* with section-area = ...	10.62 sq in
Three 9/16 by 24-in plates, with section-area of 13.50 sq in each = ...	40.50 sq in
Total section-area of upper flange = ...	56.12 sq in

To proportion the lower flange, allowance must be made for the loss in area due to two rivet-holes.

From Table I, page 702, the area of two 7/8-in rivet-holes in a 9/16-in plate (thickness of angles) = ...	1.12 sq in
Area† of two rivet-holes in three 5/8-in flange-plates = ...	3.75 sq in
Total rivet-area = ...	4.87 sq in

Hence the gross section-area of the lower flange must be $53.5 + 4.87 = 58$ sq in.

This may be made up of

One-sixth of net section-area of two webs = ...	5.0 sq in
Two 5 by 5 by 9/16-in angles, with section-area = ...	10.62 sq in
Three 5/8 by 24-in plates, with section-area of 15 sq in each = ...	45.00 sq in
Total section-area of lower flange‡ = ...	60.62 sq in

The length of the flange-plates is determined from the bending-moment diagram. Draw a horizontal line through C (Fig. 19) and at any point, as 3, lay off to any convenient scale and angle, a line $3\,H = 60.62$ units in length, with its upper extremity on the horizontal line FG drawn through C. Divide this line into five parts: $3\,I$, containing 5 units for the web-area; IJ, 10.62 units for the angles; and JK, KL and LH of 15 units each, for the three plates. Draw horizontal lines through the points I, J, K and L as shown. The horizontal intercepts of these horizontals in the bending-moment diagram will give the theoretical lengths of the flange-plates. For practical considerations, the inner plate is always carried the full length of the girder and the other plates are extended beyond the intersection-points on either side, a distance sufficient to take enough rivets to transmit at least one-third of the resistance of the plate. The resistance AS, of the outer plate is 15 sq in $\times$ 14 000 lb per sq in = 210 000 lb. One-third of this, or 70 000 lb, must be resisted by rivets placed beyond the points AA. From Table III, page 419, at 10 000 lb per sq in, the shearing value of a 7/8-in rivet in single shear plate is 6 010 lb and in a 7/8-in plate its bearing value at 18 000 lb per sq in is 9 820 lb. Hence the number of rivets required is 70 000/6 010 = 12, or 6 on each side. With a 2-in pitch this would lengthen the plate 12 in at each end. The upper plate in this particular girder would be still farther extended so as to come under the base of the column on the left side of the girder.

* Angles with equal legs are selected because the same number of rivets will be required in both legs, as they are all in single shear, and large angles are selected because the rivets will have to be staggered, owing to the concentrated loads being placed so near the ends of the girder.

† Since 9/16-in plates are selected for the upper flange, it is reasonable to suppose that 5/8-in plates will be necessary for the lower flange.

‡ Both flange-areas are made slightly in excess of the requirements, because in this example one-sixth of the web-area is included.

Fourth Step. The Stiffeners. From Table III, page 705, the safe buckling value of a ½ by 36-in plate with two ⅞-in rivets is 62 320 lb, and as this is much less than the shearing value, stiffeners must be used. The stiffeners under the concentrated loads may be considered as short struts in direct compression. Assuming that 4 by 4 by ½-in angles are used for the stiffeners, the safe load from Table XV, page 502, is over 20 000 lb. The greatest concentrated load is 90 000 lb, and hence four stiffeners will be placed under each column. Four more will be placed at each bearing, as shown in Fig. 19, four on each side, between the columns, about 4 ft on centers; and two on each side, between the columns and the bearings, making 15 on each side, or 30 in all.

Fifth Step. The Number and Pitch of the Rivets. In a box girder, the rivets are in single shear. The shearing value of a ⅞-in rivet at 10 000 lb per sq in is, from Table III, page 419, 6 010 lb, and its bearing value at 18 000 lb per sq in, in a $\frac{7}{16}$-in plate, the thinnest outside plate, is 6 880 lb; hence the shearing value will govern.

The number of rivets depends upon the horizontal flange-stress, which is equal to the maximum bending moment divided by the depth of the girder (Formula (1), page 683). M at 1 = 956 ft-tons, and the horizontal flange-stress = 956/3 = 319 tons, or 638 000 lb. From Formula (5), page 687, the number of rivets required = 638 000/6 010 = 106, or 53 on each side. These are to be spaced in a distance of 8 ft, or 96 in, which makes the pitch about 1.8 in. As this is less than the minimum pitch, 2⅝ in, or three diameters, the rivets will have to be staggered. Hence the justification for selecting large angles with equal legs for this paricular girder. At X the horizontal flange-stress = 1 123.8/3 = 374.6 tons, or 749 200 lb, and the number of rivets is 749 200/6 010 = 124, or 62 on each side; 53 of these, however, are required between R_1 and 1, leaving 9 to be placed between 1 and X, a distance of about 9 ft. As the resulting pitch will exceed the maximum pitch, they will be placed 6 in on centers between 1 and X. At 4 the horizontal flange-stress = 1 026/3 = 342 tons, or 684 000 lb. The number of rivets is 684 000/6 010 = 112, or 56 on each side, to be spaced in a distance of 12 ft, or 144 in, making the spacing 2.5 in. Between 4 and X the maximum pitch will be determined as before.

Sixth Step. The Weight of the Girder. So far, no account has been taken of the weight of the girder. The practice is to neglect this weight when the maximum bending moment due to it alone is less than 10% of the maximum bending moment due to the loads. From Formula (7), page 688, the weight of the girder = 205 × 40/700 = 12 tons. From Case V, page 326, the maximum bending moment due to it = 12 × 40/8 = 60 ft-tons. As this is much less than 10% of 1 123.8 ft-tons, the maximum bending moment due to the loads, it may be neglected. Had it been otherwise, the weight would have to be considered as an additional uniformly distributed load over the entire girder and a new bending-moment diagram drawn.

Other Data on Riveted Girders. By applying the principles illustrated in the preceding examples it is possible to compute the necessary dimensions and details for riveted girders under any conditions of loading. If further examples are desired, the reader is referred to "Compound Riveted Girders," by William H. Birkmire, in which different examples of loading are fully worked and explained, and also to other recent treatises on this subject.

Detail Drawings and Stress-Diagrams of one of the earlier heavy plate girders used in building-construction are published in the Engineering Record of Dec. 28, 1895. This girder is one of six plate girders used in the construction of Tremont Temple, Boston, Mass., Blackall & Newton, architects. The girder is 75 ft long between centers of columns, 6 ft 1 in deep, with flanges 28 in

wide, and is calculated to support distributed and concentrated loads aggregating 497.5 tons. The single web-plate is 64¾ in deep, and ⅞ in thick at the ends; the flanges are 4½ in thick at the middle of the girder; and the flange-angles are 6 by 8 by 1 in. Since that time there have been erected for many of the large buildings a number of riveted girders of very great size and strength, and details of their construction may be found in the engineering and architectural periodicals.

6. Tables Used in the Design of Plate and Box Girders

Tables I, II, III and IV contain data usually required for the design of plate and box girders to satisfy all but the most unusual conditions.

Table I.*† Sectional Area in Square Inches to be Deducted from Plates and Angles for Rivet-Holes

Taken ⅛ inch in excess of diameter of rivet ‡

	3 200	3 800	4 300	4 900	5 500	6 600	7 700
	Deductions in pounds for one 7/8-in rivet†						
	3 700	4 400	5 000	5 600	6 200	7 500	8 700

* For explanation of tables, see Subdivision 4, page 688.

† The area of the hole is taken 1/8 in in excess of the diameter of the rivet to allow for injury of the metal sustained by punching.

Example 4. What is the safe shearing value of a 36 by 3/8-in web-plate with seven 3/4-in rivets in the stiffeners?

Solution. The gross shearing value = 135 000 lb
The deduction for seven rivets = 7 × 3 200 = 22 400 lb
The safe shearing value = 112 600 lb

To use this table for any other unit stress, divide the shearing value by 10 000 and multiply by the given unit stress. For example, what is the safe shearing-value of a 40 by 5/8-in web-plate at 12 000 lb per sq in? (250 000/10) × 12 = 300 000 lb.

Tables of Riveted Steel Plate Girders.‡ It is not practicable to give TABLES OF SAFE LOADS for riveted steel plate girders because of the great variety of combinations of plates and angles that can be selected for any given condition of loading. Moreover, any variation in the loading would make the tables useless. In place of the safe loads, therefore, the PROPERTIES OR ELEMENTS OF RIVETED STEEL PLATE GIRDERS are given in Table IV, pages 706 to 716, which will aid in determining the size of the girder and the approximate thickness of the plates and angles for any special case. To determine the dimensions and other details of a girder suitable to carry any specified loading, determine the MAXIMUM END-REACTION in pounds and the MAXIMUM BENDING MOMENT in inch-pounds. Select from Table IV the different parts for a girder of the required DEPTH, a THICKNESS OF WEB as determined by the maximum end-reaction and a suitable SECTION-MODULUS as determined by dividing the maximum bending

‡ For tables of riveted single-beam girders and double-beam girders, see Tables XIV and XV, pages 605 to 611.

moment by the PERMISSIBLE UNIT STRESS FOR FLEXURE in pounds per square inch. The SPACING OF THE RIVETS, the number and position of the STIFFENERS, the LENGTH OF THE FLANGE-PLATES, if more than one are needed, and the LOSS IN FLANGE-AREA and WEB-AREA due to the punching of the RIVET-HOLES, must be determined in each case by the rules already given. The weights of the rivets and stiffeners are not included.

As an illustration of the use of these elements or properties, in Example (1) the total load on the girder is 107 000 lb, making each end-reaction 53 500 lb. The maximum bending moment is 334.8 ft-tons, or 8 035 000 in-lb. The section-modulus $I/c = M/S = 8\,035\,000/14\,000 = 574$. The depth of the girder is limited to 36 in. Looking up the properties of 36-in girders in Table IV, page 709, it is seen that a 3/8-in web is more than sufficient to resist the end-reaction. The nearest section-modulus to 574 is 567.2, that of a girder composed of a 36 by 7/16-in web, 5 by 3½ by ½-in angles, and 12 by ½-in flange-plates. In working out the problem in detail it was found that the girder required 5 by 3½ by 7/16-in angles and two 12 by ½-in flange-plates to compensate for the loss of area due to the punching of the rivet-holes.

Table III.* Safe Buckling Values of Web-Plates

SAFE UNIT BUCKLING VALUE IN POUNDS PER SQUARE INCH

Calculated by formula† $S_b = \dfrac{10\,000}{1 + \dfrac{d^2}{3\,000\,t^2}}$

S_b = safe buckling resistance in pounds per square inch; d = depth of web in the clear between flange-plates in inches; t = thickness of web in inches

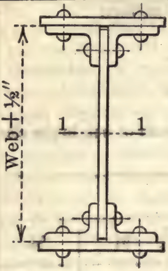
* For explanation of tables, see Subdivision 4, page 688.

† See in Chapter XV the paragraphs and foot-notes, pages 568 and 569, relating to the web-buckling of I-beams. The formula for the above table is the formula that was used in the Passaic Steel Company's Manual, and as the values computed by it vary but little from those deduced by the Cambria formula, Table III is retained as it is.

See, also, page 686, paragraph relating to Safe Resistance of Web to Buckling.

Table IV.* Elements of Riveted Plate Girders



To determine the details of construction of a girder suitable to carry any specified loading, determine the maximum end-reactions in pounds and the maximum bending moment in inch-pounds

Select from the table a girder having the desired depth, a thickness of web as determined by the maximum end-reaction and a suitable section-modulus, determined by dividing the maximum bending moment by the permissible unit bending fiber-stress in pounds per square inch

For limiting conditions, see the preceding page and the first two subdivisions of this chapter

Weights given do not include stiffeners, rivet-heads, or other details

CHAPTER XXI

STRENGTH AND STIFFNESS OF WOODEN FLOORS

By
THOMAS NOLAN
PROFESSOR OF ARCHITECTURAL CONSTRUCTION, UNIVERSITY OF PENNSYLVANIA

The Problems Stated. The problems which are presented in this part of building-construction are, in general, (1) the designing of the joists and girders forming the framework of the floor to safely support the greatest load likely to come upon it, and (2) the determination of the maximum safe load for a floor already built. The first of these problems is the one with which architects and builders more commonly have to deal, and is, therefore, considered first.

Layout of the Floor-Framing. Before any calculations can be made for the sizes of the timbers it is necessary to know the spans of the joists, and, if there are openings in the floor, or the floor-joists have to support longitudinal partitions, a framing-plan should be made, showing the floor-area that will be supported by each joist, and also the position of partitions or special loads. If the floor is to be supported by posts and girders the position of these should also be accurately indicated on the framing-plan.* Where the joists are supported entirely by walls or partitions, the spans of the joists will of course be fixed by the plan of the building. When the distance between a wall and a partition is too great for a single span, there may be a question as to the best locations for the posts and girders. When planning a building in which wooden joists are to be used, it is important to keep in mind the general scheme of the floor-framing and particularly the spans. Whenever practicable the spans of wooden joists should not exceed 24 ft. When the distance between the supporting walls exceeds 30 ft, girders should be placed so that the maximum span of the joists will not exceed 24 ft for light buildings nor from 16 to 18 ft for warehouses.

In School Buildings it is desirable to have the rooms at least 27 ft wide, and hence in this class of buildings the joists usually have spans of from 27 to 30 ft. For a span of 30 ft, however, 16-in joists should be used, and as these are expensive, and often difficult to obtain, it is much better and more economical to make the schoolrooms 27 by 32 or 34 ft, than to make them 30 ft square. A schoolroom 27 ft wide by from 32 to 34 ft long, with windows on the long side, only, is economical and satisfactory, as it permits of using 3 by 14-in joists, 28 ft long, and also results in the most satisfactory lighting.

Continuous Joists. When joists are supported by a girder placed so that a 24-ft or 26-ft joist extends over the two spans, it is always better to have the joists continuous over the girder, as by that construction they make a much stiffer floor. (See Chapter XIX.)

Floor-Loads. Having decided on the arrangement of the joists, and drawn a framing-plan showing the span and the locations of all special timbers, the

* For a detailed description of the manner of framing wooden floors the reader is referred to Building Construction and Superintendence, Part II, Carpenters' Work, by F. E. Kidder.

next step involves the determination of the loads for which the joists and girders are to be proportioned. Floor-loads are made up of two parts, the weight of materials composing the floor itself, and the ceiling below, if there is one; and the load liable to be put on the floor. The first is called the DEAD LOAD, and the second the LIVE LOAD. When the SAFE LOAD for a floor is spoken of the live load is generally meant.

Weight of Wooden Floor-Construction. Wooden floors usually consist of (1) beams, commonly called JOISTS,* or FLOOR-JOISTS, (2) one or two thcknesses of flooring-boards, and, in a finished building, (3) a ceiling underneath the joists. In figuring the weight of ⅞-in flooring-boards it will be sufficiently accurate to estimate the weight of a single thickness at 3 lb per sq ft. The joists may also be figured at 3 lb per ft, board-measure, with the exception of hard-pine and oak joists, which should be figured at 4 lb per ft, board-measure. The weight of the joists must also be reduced to their equivalent weight per square foot of floor. Thus, the weight of a 2 by 12-in joist is about 6 lb per lin ft. If the joists are spaced 12 in on centers, this will be equal to 6 lb per sq ft; but if the joists are 16 in on centers there will be but one lineal foot of joist to every 1⅓ sq ft, which will be equivalent to 4⅞ lb per sq ft; and if they are 20 in on centers, the weight will be equal to 3⅗ lb per sq ft; spaced 24 in on centers, the weight will be 3 lb per sq ft. The weight of a lath-and-plaster ceiling should be taken at 10 lb per sq ft, and of a ¾-in wooden ceiling at 2½ lb per sq ft. A corrugated-iron ceiling weighs about 1 lb per sq ft. For stamped-steel ceilings, 2 lb per sq ft will cover the weight of the metal and furring. The following table, giving the weight of joists, will be found convenient in figuring the weight of floors:

Table I. Weight of Floor-Joists per Square Foot of Floor

Sizes of joists	Spruce, hemlock, white pine		Hard pine or oak	
	Spacing in inches, center to center		Spacing in inches, center to center	
	12	16	12	16
in	lb	lb	lb	lb
2× 6	3	2¼	4	3
2× 8	4	3	5⅓	4
3× 8	6	4½	8	6
2×10	5	3¾	6⅔	5
3×10	7½	5½	10	7½
2×12	6	4½	8	6
3×12	9	6¾	12	9
2×14	7	5¼	9⅓	7
3×14	10½	8½	14	10½

Weight of Crowds. I. J. Johnson reports † results of some tests to ascertain the weight of crowds of men, in which he obtained weights of 134.2, 143.9,

* Some building laws use the term FLOOR-BEAM instead of the word JOIST.
† See Engineering News, April 14, 1904.

148.1 and 156.9 lb per sq ft. The last-mentioned weight was obtained by packing 67 men in a room about 6 by 11 ft in size. Professor Johnson also found that with 50 men in the room, making a load of 122 lb per sq ft, the crowd was compacted "so that a man could elbow his way through it only with perseverance and determined effort."

Superimposed Loads. There is much difference of opinion as to what allowance should be made for the live load. Table II shows the minimum allowance for live loads for different classes of buildings, as fixed by the building laws of the cities mentioned. (See, also, page 149.)

Table II. Minimum Safe Superimposed Loads for Floors, Required by Various Building Laws

Classes of buildings	Minimum live load per square foot of floor					
	Buffalo, 1905	Boston, 1912	Chicago, 1911	Philadelphia, 1913	New York, 1906	St. Louis, 1910
Dwellings	40	50	40	70	60	60
Hotels, tenements and lodging-houses	70	50	50	70	60	60
Office-buildings	70	100	50	100	75 *	70 *
Buildings for public assembly	100	200	100	120	90	100 †
Stores, warehouses and mfg. bldgs.	120 ‡	125 ‡	100 ‡	120 ‡	120 ‡	150 ‡

* First floor, 150 lb. † Also schoolhouses. ‡ And upwards.

It was the opinion of Mr. Kidder that the following allowances for floor-loads, taken in connection with the values given for the safe strength of joists or beams, provide absolute safety with proper allowance for economy.

	Lb per sq ft
For dwellings, sleeping-rooms and lodging-rooms	40
For schoolrooms	50
For office-buildings, upper stories	60
For office-buildings, first story	80
For stables and carriage-houses	65
For banking-rooms, churches and theaters	80
For assembly-halls, dancing-halls and the corridors of all public buildings, including hotels	120
For drill-rooms	150

Live Loads for Stores and Buildings for Light Manufacturing. Floors for ordinary stores, light manufacturing and light storage should be computed for not less than 120 lb per sq ft, and for a concentrated load at any point of 4 000 lb.

Live Loads for Dwellings, etc. Floors of dwellings, tenements, lodging-houses and rooms in hotels, are seldom loaded with more than 20 lb per sq ft for the entire area, and a minimum load of 40 lb per sq ft should provide for all possible contingencies.

Live Loads for Office-Buildings. The floors of offices are, as a rule, not more heavily loaded than the floors of dwellings, but the possibilities for increased loads from safes and heavy furniture, and possibly from a more compact crowd of people, are greater, so that the minimum floor-load for offices should be somewhat increased. Some years ago the firm of Blackall & Everett, in Boston, found that the average live load in 210 offices, in three prominent office-buildings in that city, was between 16 and 17 lb per sq ft, while the average load for the 10 heaviest office-buildings was 33.3 lb per sq ft. As such loads, however, are as a rule unevenly distributed, some portions of the floor being generally much more heavily loaded than others, it would not appear to be safe to use this average to determine the strength of floor-beams and floor-arches, although it would probably answer for the columns. There seems to be a considerable difference of opinion among the leading architects and structural engineers as to just what allowance should be made for office-floors. Among some of the earlier fire-proof office-buildings, for example, may be mentioned the former Mills Building in San Francisco in which the live loads were assumed at 40 lb per sq ft for all floors above the first. In the Venetian Building, Chicago, the second, third and fourth floors were calculated for 60, and the upper floors for 35 lb per sq ft of live load, while in the Old Colony and Fort Dearborn Buildings in Chicago, the live loads on the floor-beams were assumed at 70 lb per sq ft. At the present time (1915), 50, 60, 70, 75, 100 and 150 lb per sq ft are the minimum live loads for the design of floors of office-buildings required by the building laws of six different cities. C. C. Schneider recommends* for the design of floors of office-buildings above the first floor, for the uniform load of the floor-area, 50; for concentrated loads applied at any point of the floor, 5 000; and for the uniform load for girders, 1 000; the 50 being in pounds per sq ft, the 5 000 in pounds and the 1 000 in pounds per linear foot.

Live Loads for Churches, Theaters and School-Houses. "An allowance of 120 lb per sq ft for the live load in churches, theaters and school-houses is much greater than the actual conditions require. The average size of a schoolroom is about 28 by 32 ft, and such a room usually contains seats for fifty-six scholars and the teacher. Assuming the average weight of each scholar at 120 lb, the average live load, including ten visiting adults and the desks and furniture, is 13 lb per sq ft. Even supposing that the scholars of two rooms were united for some special occasion, there would be only 22 lb per sq ft; and this is as great a load as it is possible to imagine in such a room, as the fixed desks prevent the crowding together of the scholars except at the sides of the room. From this reasoning, therefore, 50 lb per sq ft would appear ample for schoolrooms. As a matter of fact, 3 by 14-in long-leaf yellow-pine joists, 16 in on centers and with a 28-ft span, have been used for school-room floors for years; but such beams, if calculated by the formula for stiffness, would support a live load of only 43 lb per sq ft. (Table XII, page 643 and Table I, page 718.) The minimum floor-space allotted to a single seat in theaters is 4 sq ft, while the average is about 5 sq ft. Assuming the weight of an opera-chair at 35 lb and of the average adult at 140 lb, a liberal allowance, there results an average of 44 lb per sq ft of floor. A minimum of 80 lb per sq ft would therefore seem to provide for any possible crowding during a panic, except in corridors. On the other hand, it has been shown (see Weight of Crowds, page 718) that a crowd of able-bodied men may result in a load of about 120 lb per sq ft, and this should be the minimum for assembly-halls without fixed desks and also for the corridors of all public buildings. For armories, the minimum load should be increased on account of the vibration."†

* "General Specifications for Structural Work of Buildings," 1910, page 57.

† F. E. Kidder.

The Average Floor-Loads for Stores has also been greatly over-estimated. W. L. B. Jenney found that the average load on the floors of the wholesale warehouse of Marshall Field & Company, in Chicago, was but 50 lb per sq ft, and very few retail stores will average over 80 lb per sq ft. An allowance of 120 lb per sq ft is sufficient for ordinary retail stores, with the possible exception of hardware stores.

Live Loads for Warehouses. Warehouses, on the other hand, may be very heavily loaded, and the floors in buildings intended for the storage of merchandise should be proportioned to the especial class of goods which they are designed to support. Table III, originally compiled by C. J. H. Woodbury,* and to which some additions have been made by the Insurance Engineering Experiment Station and by Mr. Kidder, will be found of assistance in deciding upon the live load to be assumed for warehouse-floors. The weights per square foot are for single packages. If the goods are piled two or more cases high, the weight per square foot of floor will of course be increased accordingly. In fact, the height to which the goods are liable to be piled is a very important consideration in fixing upon the floor-load. In Table III "the measurements were always taken to the outside of case or package, and gross weights of such packages are given."

Methods of Determining the Sizes of Joists, Beams or Girders Required for Any Building. As already explained, the first step is the making of a framing-plan of the floors or enough of it to show any special framing and also the span and floor-area supported by the different joists, beams or girders.

* For pressure of grain in deep bins, see Engineering News, March 10, 1904, pages 224 and 336, and Dec. 15., 1904.

The second step is to determine approximately the weight of the floor and ceiling, and decide what superimposed load per square foot the floor is to be designed to carry. Having done this, the next step is the computing of the required dimensions of the common floor-joists. For most buildings the size of floor-joists required can be readily determined by reference to Tables XIII to XVII, inclusive, and XXII to XXVI, inclusive, of this chapter. For other floor-loads the sizes of the common joists may be determined by computing the load to be supported by a single joist and then, by the formulas or tables in Chapter XVI or the formulas in Chapter XVIII, determining the dimensions of the joists to support that load. (See Example 1.) For the floors of all buildings except stores and warehouses it is recommended that the sizes of the common joists be determined by the formulas for stiffness in Chapter XVIII or the stiffness-values in the tables in Chapter XVI, unless one value, only, is given in tables for safe loads, in which case that value may be used. For stores and warehouses the sizes of the joists may be proportioned by the formulas or strength-values of the tables in Chapter XVI.

The Dimensions of Special Beams, such as headers, trimmers and beams supporting partitions, and also of the girders, should be determined in the same way, that is, by computing the maximum load the beam may have to support, and then the dimensions of a beam that will support that load with safety. The manner of making the computations is explained in the following examples.

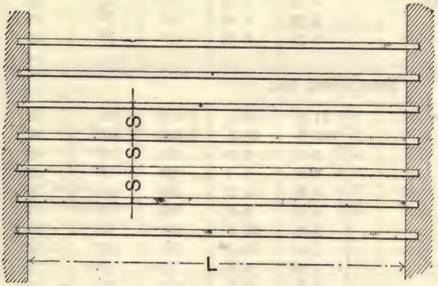

Fig. 1. Plan of Floor-joists

Example 1. The simplest type of floor-framing is that shown in Fig. 1, in which all of the joists are of the same span and support equal floor-areas. In such a floor, the FLOOR-AREA supported by each joist is equal to the span, L, multiplied by the spacing, S, in feet. The LOAD on each joist is equal to the FLOOR-AREA multiplied by the sum of the dead-loads and superimposed or live loads. To show the application of the above-mentioned formulas and tables we will assume that Fig. 1 represents the framing of a floor in a dwelling-house or lodging-house, that $L = 18$ ft, $S = 16$ in or $1\frac{1}{3}$ ft, and that the timber is common white pine. The joists are to support a plastered ceiling and a double floor of ⅞-in boards. What should be the size of the joists; average quality, conditions not ideal?

Solution. The FLOOR-AREA supported by each joist is $1\frac{1}{3}$ by 18, or 24 sq ft. From Table XIII or XXII, pages 737 and 742, for a span of 18 ft, the joists will probably have to be at least 2 by 12 in, and their weight will be about 4½ lb per sq ft (see Table I, page 718). The plastered ceiling weighs about 10 lb and the flooring 6 lb per sq ft, making the total weight of the floor 20½ lb per sq ft. For the superimposed load we should allow at least 40 lb per sq ft (see page 719). This might be greater, if exacted by any particular building law. The load on a single joist will, therefore, be, with these assumed unit loads, 60½ lb by 24 sq ft, or 1 452 lb.

From Table VIII, page 639, we find that the maximum load for a 1 by

12-in white-pine joist of 18 ft span is 623 lb; hence to support 1 452 lb will require a breadth equal to 1452/623 = 2⅓ in. Therefore, to comply with the requirements for both strength and stiffness, the joists should be 2⅓ by 12 in.

This is not a stock size. Joists 2 by 12 in, 12 in on centers, may next be tried. Each joist must support 1 116 lb, requiring, by Table VIII, page 639, a 1.8 by 12-in joist, determined by the quotient 1 116/623. So that, in this example, white-pine joists of a nominal size of 2 by 12 in and spaced 12 in on centers might be used, although they are slightly under the required depth, as the dressed size is about 1¾ by 11½ in. From Table VI, page 637, the conversion-factor is 1.61, and 623 lb × 1.61 = 1 003 lb which is less than 1 116 lb, the load to be supported. From Tables XIII and XXII, pages 737 and 742, the maximum spans for 2 by 12 in white-pine joists, 12 in on centers, are 19 ft and 18 ft 8 in respectively, according to the assumed value of the modulus of elasticity for white pine. For 3 by 12-in joists, 16 in on centers, the load is 1 506 lb, and 1 506/623 = 2⅖ in. The dressed size is almost 2¾ by 11½ in, the conversion-factor, 2.53, and 623 × 2.53 = 1 576 lb, an amount greater than 1 506 lb. Tables XIII and XXII, again, give 19 ft 8 in and 19 ft 4 in for the maximum spans. Joists 3 by 12, 16 in on centers, are stronger than necessary. If, in this example, the span is made 20 ft, by Table VIII, page 639, for 12-in joists two values for the safe loads are found, and the smaller, stiffness-value, should be used, unless the deflection need not be considered.

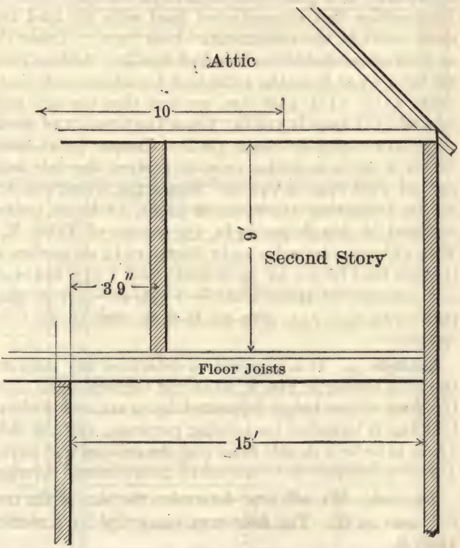

Fig. 2. Section Through Floors and Partitions

Example 2. Fig. 2 shows a partial section of a dwelling, in which the second-floor joists support a plastered partition which also supports the attic joists. What should be the size of the second-floor joists to meet the requirements of STRENGTH, the timber being fair-quality Eastern spruce with a safe fiber-stress assumed to be 700 lb per sq in for flexure? As the effect of a concentrated load, compared with a distributed load, in producing deflection, is not as great as the comparative effect in producing rupture, whenever a beam has a considerable CONCENTRATED load it may be calculated by the formula or tables FOR STRENGTH ONLY. The timber is assumed to be poorly seasoned.

Solution. The first step will be to determine the load on a single floor-joist. We will assume, as a trial, that the joists are to be 2 by 10 in, 12 in on centers, that both the first-story and second-story ceilings are to be plastered, and that

only single flooring will be used in the second story and attic. We will assume that the attic-joists are to be 2 by 8 in, 16 in on centers, and that the width of floor supported by the partition is 10 ft.

The second-floor area supported by a single joist is 12 in by 15 ft, or 15 sq ft. The weight of the floor-joists per sq ft is 5 lb, of the plastered ceiling 10 lb and of the flooring 3 lb, making the dead load per sq ft 18 lb. For the live or superimposed load we should allow 40 lb and hence the load per square foot on each second-floor joist due to the second floor and its load is 58 lb. As the floor-area for a single joist is 15 sq ft the load from the second floor is 15 sq ft by 58 lb per sq ft or 870 lb on each joist. We must now find what will be the load from the partition and attic-floor. The attic-floor and ceiling weigh about 16 lb per sq ft, and 24 lb is a sufficient allowance for the live load. The weight per linear foot on the partition will therefore be 400 lb. A partition of 2 by 4-in studs, lathed and plastered on both sides, weighs about 20 lb per sq ft of face; hence the partition itself weighs 180 lb per lin ft. The partition and attic-floor, therefore, bring a load of 580 lb on each second-floor joist, CONCENTRATED at a point ONE-FOURTH of the span from the inner end of the joist. To combine this concentrated load with the load from the second floor, we must multiply the concentrated load by 1.5 (Table IV, page 632), which gives an equivalent distributed load of 870 lb. Adding this to the second-floor load we have 1 740 lb as the total load for which each joist should be proportioned. From Table VIII, page 639, we find that the safe load for a 1 by 10-in spruce joist of 15-ft span is 518 lb; hence the breadth of each joist should be equal to 1 740/518 = 3.36 or about 3⅓ in. Deeper joists, therefore, must be used. If we try 2 by 12-in joists, 12 in on centers, the safe load for a 1 by 10-in spruce joist of 15-ft span is 747 lb. Hence the breadth is 1 755/747 = 2.35 or about 2⅓ in, indicating 2⅓ by 12-in joists, 12 in on centers. If the fiber-stress is assumed at 800 lb per sq in, the values of Table X, page 641, may be used. This will give, for 2 by 12-in joists, 12 in on centers and 15-ft span, 850 lb for the safe load for a 1 by 12-in joist; and 1 755/850 = about 2 in. The load per sq ft on each of these joists is 1 755/15 = 117 lb; and Tables XVI and XXV, pages 739 and 744, give 16 ft 6 in and 16 ft 1 in for the maximum safe spans.

Example 3. It is required to determine the sizes of the girders and joists in the floor shown in Fig. 3, all of the timbers being of long-leaf yellow pine, and the floor above being supported by posts and girders in the same way. The building is intended for lodging purposes, and the height of the story is 10 ft. There is to be a double floor and the ceilings and partitions are to be plastered. The floor-joists are to be spaced 16 in on centers. Average timber, poorly seasoned.

Solution. We will first determine the size of the common joists at A, calling the span 24 ft. The floor-area supported by a single joist is 24 by 1⅓ ft, or 32 sq ft.

From Table XIII or XXII, pages 737 and 742, for a 24-ft span, 2½ by 14-in joists are probably required. We will allow 8¾ lb per sq ft for the weight of joists and bridging (Table I, page 718), 10 for the ceiling and 6 for the flooring, making 24¾ lb per sq ft for the dead load. For the live load we will allow 40 lb per sq ft. The load for which the joists should be proportioned is, therefore, 32 by 64¾ or 2 072 lb. We may use Table XII, page 643, to find the maximum load for a 1 by 14-in joist of 24-ft span. The deflection-load given in the table is 882 lb; hence the thickness of the joists must equal 2 072/882 = 2.35 or about 2⅓ in. Therefore 2½ by 14-in long-leaf yellow-pine joists, 16 in on centers, may be used, but they should run full 2½ in thick. The joists at B (Fig. 3) have to support a partition, but as the span is much less, and the

partition is quite near the end of the joists, it will be safe to make them of the same size as at *A*.

The joists at *C* (Fig. 3) have the same floor-load to support as at *A*, and in addition the weight of the partition, which is concentrated at one-third of the span from one support. As the partition is 10 ft high, 13⅓ sq ft of partition will be supported by each joist, the joists being 16 in on centers. Assuming 20 lb

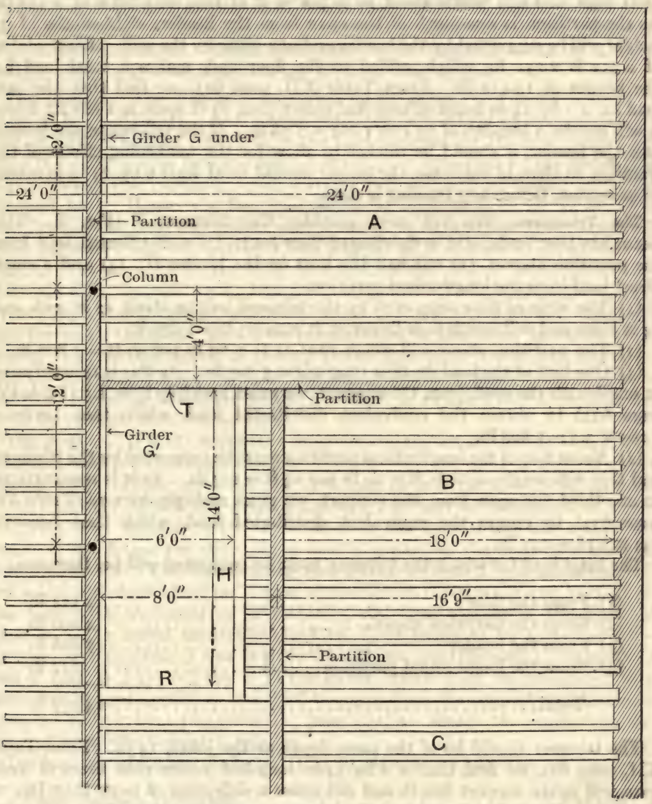

Fig. 3. Plan of Floor-framing Showing Partitions Above

per sq ft of face as the weight of the partition, we have 267 lb as the weight from the partition to be borne by each joist. To reduce this to an equivalent distributed load, we should multiply by 1.78 (Table IV, page 632), which gives 468 lb. The joists at *C*, therefore, should be proportioned to a uniformly distributed load of 2 072 + 468 = 2 540 lb, which requires 14-in joists, 2.88 in thick, or, say, 3 by 14-in joists.

The Header. We will next determine the required breadth for the header, H (Fig. 3), the depth being necessarily 14 in, the same as for the joists.

The header is 14 ft long and must support the floor half-way to the wall, or a floor-area of 14 by 9 ft, or 126 sq ft. Multiplying this area by 64¾ lb, the weight per square foot, we have 8 159 lb, the total floor-load to be supported, to which must be added a certain percentage of the partition. The portion of the partition supported by the header is (14 ft − 1 ft 4 in) = 12 ft 8 in long and 10 ft high, and will weigh about 20 lb per sq ft of face, or a total of 2 532 lb. As the partition is one-ninth of the span from the header, eight-ninths of its weight will be supported by the header and one-ninth by the wall. Eight-ninths of 2 532 is 2 251 lb, which, added to the floor-load, makes a total load for the header of 10 410 lb. From Table XII, page 643, we find that the safe load for a 1 by 14-in beam of long-leaf yellow pine, 14-ft span, is 1 867 lb; hence it will require a breadth of 10 410/1 867 = 5.58 in. If the tail-beams are framed into the header, it should be thicker to allow for the weakening effects of the framing; so that, in this case, the header should be at least 6 by 14 in in actual cross-section, before any framing is done.

The Trimmers. We will next consider the trimmer, T (Fig. 3). This beam has four loads: (1) a distributed floor-load; (2) a distributed load from the partition above; (3) one-half the load on the header H; (4) and a small direct load from the longitudinal partition.

(1) The strip of floor supported by the trimmer will be about 12 in wide and 24 ft long, and will weigh 64¾ lb per sq ft × 24 sq ft = 1 554 lb.

(2) The partition above will weigh 10 × 24 ft × 20 lb per sq ft = 4 800 lb.

(3) One-half of the load on H is 10 410/2 = 5 205 lb. As this is concentrated at one-fourth the span from the support, we must multiply it by 1.5 (Table IV, page 632) to obtain the equivalent distributed load, which then becomes 5 205 × 1.5 = 7 808 lb.

(4) About 8 in of the longitudinal partition must be supported by the trimmer, and this will weigh 10 × ⅔ ft × 20 lb per sq ft = 133 lb. As it is concentrated at one-third the span from the support, we must multiply by 1.78 (Table IV, page 632) to obtain the equivalent distributed load, which then becomes 133 × 1.78 = 237 lb.

The total load for which the trimmer must be computed will be, therefore:

(1) From the floor	1 554 lb
(2) From the partition above	4 800 lb
(3) From the header	7 808 lb
(4) From the longitudinal partition	237 lb
Total	14 399 lb

The trimmer should be of the same depth as the joists, 14 in. From Table XII, page 643, we find that a 1 by 14-in long-leaf yellow-pine beam of 24-ft span will safely support 882 lb and not cause a deflection of more than 1/360 of the span. Hence, the breadth of the trimmer would be 14 399/882 = 16.34 in, which is greater than the depth. This would suggest the substitution of a steel **I** beam of proper size or the use of a deeper wooden beam, such as an 11 by 16 or a 12 by 16-in beam. If the deflection of the wooden beam is not taken into account, the strength-value, 1 090 lb of Table XII, page 643, may be used, giving 14 399/1 090 = 13.21 in as the width of the beam. This would agree with the New York Building Laws for strength. If the flexure fiber-stress is taken at 1 300 lb per sq in, permitted by the Chicago code, Table XIII, page 644, may be used, giving 14 399/1 179 = 12.21 in for the width of the trimmer.

If 1 800 lb per sq in is taken for S, Table XV, page 646, is used, giving 14 399/1 633 = 8.81 in for the width. Hence, the architect will be governed by laws in cities, or by engineering judgment or experience elsewhere, and this applies to the joists as well as to the girders. If wooden trimmers are used, they should be hung in beam-hangers (see last part of this chapter). The load on the trimmer, R, will be the same as on the trimmer, T, except for the cross-partition. Deducting the weight of this partition, we have 14 399 − 4 800 = 9 599 lb for the equivalent distributed load on R, which, from Table XII, page 643, gives, for the required breadth 10.88 in or 8.8 in, depending upon whether the deflection is or is not considered. Other variations in the required width of a 14-in wooden girder will result from the use of other fiber-stresses.

The Girders. The floor-area supported by the girder, G (Fig. 3), is equal to 12 by 24 ft, or 288 sq ft. As a general rule, it will be safe in estimating the live load on girders to take only 85% of the load assumed for the floor-beams, because there will always be some portion of the floor supported by the girder that is not loaded, and probably other portions that will not be loaded up to the assumed load. Hence, the live load would be 85% of 40 lb, or 34 lb. The dead load of the floor and ceiling will be about 25 lb, and the girder itself will weigh between 1 and 2 lb per sq ft, say 2 lb per sq ft of floor, more, so that we will use 61 lb per sq ft for the total floor-load on this girder. As girder G supports 288 sq ft, this will be equivalent to 17 568 lb. The girder supports, also, a partition, 9 ft high, above, which will weigh 12 × 9 × 20 = 2 160 lb. The total load for which the girder should be proportioned is, therefore, 19 728 lb. Assuming 14 in for the depth of the girder, we find from Table XII, page 643, that the safe load for a 1 by 14-in long-leaf yellow-pine beam of 12-ft span is 1 867 lb; hence the breadth of girder, G, should be 19 728/1 867 = 10.56 in and an 11 by 14-in girder could be used.

The girder, G' (Fig. 3), supports a floor-area at the left of 12 × 12 = 144 sq ft, which represents a distributed load of 8 784 lb. On the right side of the girder there is a strip of floor 40 in wide by 12 ft long (8 in of the floor being included in the load on T) which will weigh 2 440 lb. This may be considered as a concentrated load applied 20 in, or one-seventh the span, from the end of the girder, in which case the effect of the load is practically the same as if the load were distributed. The load coming upon girder G' from T will equal one-half the actual distributed load on T, plus three-eighths (½ of ¾) of the load on H. The load on H we found to be 10 410 lb, and three-eighths of this is about 3 900 lb. The actual distributed load on T we found to be 1 554 + 4 800 = 6 354 lb, and one-half of this is 3 177 lb. Hence the trimmer, T, transmits a load of 3 900 + 3 177 = 7 077 lb to the girder, which must be considered as a concentrated load applied at one-third the span from the support, and hence we must multiply it by 1.78 (Table IV, page 632) to obtain the equivalent distributed load, which gives 12 597 lb.

The load for which the girder, G' (Fig. 3), should be computed will be

From the floor at the left	8 784 lb
From the floor at the right	2 440 lb
From the trimmer, T	12 597 lb
From the partition above	2 160 lb
Total	25 981 lb

From Table XII, page 643, we find that this load will require a (13.9 by 14-in) 14 by 14-in girder. For this floor, therefore, the requirements, if long-leaf yellow pine is used, and if the maximum flexure fiber-stress, S, is

taken at 1 200 lb per sq in (a conservative value for non-ideal conditions, for example) and the modulus of elasticity, E, at 1 500 000 lb per sq in, are as follows: an 11 by 14-in girder at G; a 14 by 14-in girder at G'; an 11 by 16, or 12 by 16-in wooden beam or a steel **I** beam for the trimmer, T; an 11 by 14-in beam for the trimmer, R; a 6 by 14-in beam for the header, H; 2½ by 14-in joists at A and B; and 3 by 14-in joists at C. For these stress-requirements the architect might decide to use steel **I** beams for girders G, G', etc., and for the trimmers, T and R. For S, 1300, Table XIII, page 644, may be used for long-leaf yellow pine; for S, 1500 lb per sq in, Table XIV, page 645; for a fiber-stress, S, of 1800 lb per sq in, Table XV, page 646; and for S equal to 1600 lb per sq in, Table XII, page 643, with the strength-values increased one-third. Of course, the sizes of the timbers are diminished as the assumed safe fiber-stresses are increased.

This example illustrates nearly all of the computations that are required to determine the sizes of the joists and special beams or girders in any ordinary floor-construction. The method of computation is the same for any floor-load, the only difference being that the greater the live load assumed the greater will be the loads for which the beams must be proportioned. As will be seen, the most laborious computations are those for beams which receive loads from different sources, and it will generally be found that the weakest portions of any particular floor are the headers, trimmers and girders, and the beams which support partitions.

The Strength of Mill-Floors. The beams and girders for mill-floors should be computed by the same general method illustrated in the foregoing examples, involving, (1) the determination of the loads on the beams and girders and, (2) the sizes of the beams and girders required to support such loads.

Required Thickness of Plank Flooring. The thickness of the plank flooring in mill construction may be determined by formulas (1) and (2):

$$\left.\begin{array}{r}\text{Thickness of plank in in}\\ \text{required for strength}\end{array}\right\} = \sqrt{\frac{\text{weight per sq ft} \times l^2}{24 \times A}} \tag{1}$$

$$\left.\begin{array}{r}\text{Thickness of plank in in}\\ \text{required for stiffness}\end{array}\right\} = \sqrt[3]{\frac{\text{weight per sq ft} \times l^3}{19.2 \times e_1}} \tag{2}$$

In these formulas, l is the span in feet, from center to center of beams, A the constants for strength (page 628), and e_1 the constant for stiffness (page 664).

When the planks are connected by ¾-in splines, and extend over two spans, Formula (1) may be used. If the planks are in single lengths from beam to beam, or are not splined, then Formula (2) should be used.

Tables IV to XI,* inclusive, show the safe loads for plank flooring of different woods, thicknesses and spans, derived from the formulas for strength and stiffness, the values in the first horizontal line in the case of each thickness of plank

* Tables VIII to XI, inclusive, were calculated by Mr. F. E. Kidder and are retained from the preceding edition of the Pocket-Book. Tables IV to VII, inclusive, are added to conform to the most conservative fiber-stresses of the building codes and of the other chapters of the new edition. In the judgment of many constructors the higher values of Tables VIII to XI are safe when more favorable conditions of quality and dryness of materials prevail. In using any of the tables, care must be taken to notice whether or not the safe loads given include the weight of the flooring itself. In the revision of this chapter the author is indebted to Professor F. H. Safford, of the University of Pennsylvania, for the computations required for the new Tables IV to VII and for the checking of Tables VIII to XI.

denoting the loads given by the formula for strength and the figures in the second line those given by the formula for stiffness. The span is supposed to be measured from center to center of beams. The values given by the formula for strength should be considered safe only for splined floors and where the planks are continuous over at least two spans. If the thickness of the planks falls short ¼ or even ⅛ in from the dimensions given, the safe loads must be materially reduced.

In Table IV, the modulus of elasticity, E, on which e_1 in the stiffness-formula depends, is 1 500 000 lb per sq in, and the safe fiber-stress, S, on which the constant for strength, A, depends, is 1 200 lb per sq in, A being 67. The safe loads given are within the requirements of all cities for strength and stiffness for long-leaf yellow pine, and of Chicago and most other cities for Douglas fir.

In Table V, E is 1 200 000 lb per sq in, S, 1 000 lb per sq in, and A is 56. The loads given satisfy the requirements of Chicago and of most other cities for strength for short-leaf yellow pine. The values given for stiffness, also, are recommended for this wood.

In Table VI, E is 1 200 000 lb per sq in, S, 800 lb per sq in, and A is 44. The loads given satisfy the requirements of all cities for strength, for spruce, Norway pine and white pine, and the values given for stiffness, also, are recommended for spruce. For Norway pine, $E =$ 1 100 000 lb per sq in may be used.

In Table VII, E is 1 000 000 lb per sq in, S, 700 lb per sq in, and A is 39. The loads given for strength can be used for any woods of that safe fiber-stress, and the loads for stiffness are recommended for white pine.

In Tables VIII, IX, X and XI, the safe loads are calculated from still other values of S, A, E and e_1, indicated with each table, and may be used by those who wish to assume larger safe values for the strength and stiffness-factors in cases where there are no restrictions from building laws. For any other values of A or e_1 required, such values must be inserted in Formula (1) or (2) and the thicknesses of the planks determined or the safe load determined for any given thickness of planks.

Note. It is to be noted that for ideal conditions and commercially dry lumber, protected from moisture, and when there is no impact, the given fiber-stresses for flexure may be increased from 30 to 40%. (See, also, important notes on page 637 regarding stresses in and loads on wooden beams.)

Table IV. Safe Live Loads* in Pounds per Square Foot for Plank Flooring

See explanation on pages 730–1. The loads are based on the following values.
Strength: $S = 1\ 200$ lb per sq in, $A = 67$; stiffness: $E = 1\ 500\ 000$ lb per sq in, $e_1 = 116$

* Weight of ceiling, if any, to be deducted. The weight of the flooring has been deducted from values derived from formulas. Deduction about 72 lb per cu ft floor-material.

Table IX. Safe Live Loads* in Pounds per Square Inch for Plank Flooring

See explanation on pages 730–1. The loads are based on the following values.
Strength: $S = 1\ 620$ lb per sq in, $A = 90$; stiffness: $E = 1\ 425\ 000$ lb per sq in, $e_1 = 110$
